At the same time, recognizing that one-third to two-thirds of patients with MH will have a negative hematuria evaluation, considered together with the health system financial burden and patient risks associated with MH evaluation, efforts have been put forth to develop a more individualized approach to the selection of patients for MH evaluation (Loo et al., 2013; Mohr et al., 1986; van der Molen and Hovius, 2012). For example, data from Kaiser Permanente demonstrated that, among patients undergoing a complete evaluation for hematuria, those with risk factors for malignancy (age >50 years, history of GH, tobacco use, male gender, or >25 RBCs/HPF) had higher rates of malignancy diagnosed at evaluation (10.7% to 11.6%) than patients classified as being at intermediate (1.1% to 2.5%) or low (0% to 0.3%) risk (Loo et al., 2013). Similarly, the American College of Obstetricians Gynecologists and American Urogynecologic

Society issued a joint statement in 2017 on asymptomatic microscopic hematuria in women, recommending withholding evaluation in never-smoking women aged 35 to 50 who have fewer than 25 RBCs/HPF because the risk of urinary tract malignancy in such patients has been demonstrated to be less than or equal to 0.5% (Committee for Gynecologic Practice, 2017). Nevertheless, it is important to recognize that, despite the potential benefits of such risk-based approaches, analyses of contemporary practice patterns have noted that **fewer than 25% of patients found to have hematuria are even referred for evaluation, and fewer than 10% undergo a complete evaluation with cystoscopy and imaging,** including among patients at high risk for malignancy (Ark et al., 2017; Bassett et al., 2015; Buteau et al., 2012; Elias et al., 2010; Friedlander et al., 2014). Thus, although ample room remains for improvement in the selection of patients for MH evaluation, currently there exists a huge variation in care delivery with a large proportion of at-risk patients not being evaluated in a proper and timely fashion. Therefore continued research and education are necessary and may in fact be facilitated by the implementation of such systems as decision support tools in the electronic medical record, telemedicine consultation, and one-stop hematuria clinics (Liedberg et al., 2016; Ooi et al., 2011).

The Question of Screening for Hematuria and Bladder Cancer

Bladder cancer is the sixth most commonly diagnosed cancer in the United States, and although no large-scale screening trials have been performed, **most believe that the harms and costs of mass screening for bladder cancer would prove to outweigh the potential benefits** (Chou and Dana, 2010; National Cancer Institute, 2018). Nonetheless, many primary care providers perform urinalysis as part of routine health examinations, creating numerous opportunistic screening events (Prochazka et al., 2005).

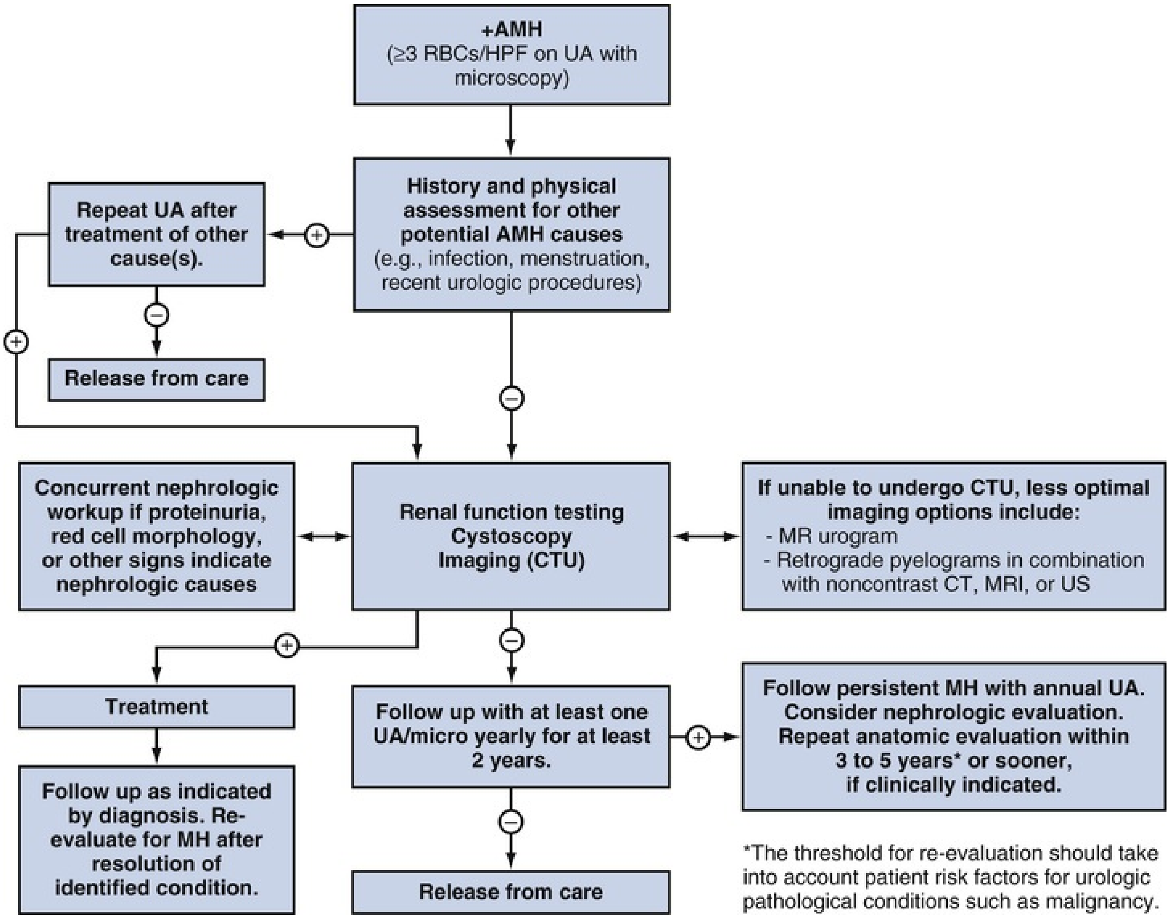
Key Points: Microscopic Hematuria

- MH is defined by the AUA guidelines as three or more RBCs/HPF, identified on one or more occasions on urine microscopy. Urine dipstick testing is insufficient for the diagnosis of MH.

- MH is common, with a prevalence of approximately 6.5% of adults, varying according to the characteristics of the population.
- Malignancy has been detected in approximately 3.5% of patients evaluated for asymptomatic MH. The risk of malignancy diagnosis is greater in patients with higher degrees of hematuria, male gender, and/or risk factors for malignancy and lower in absence of these risk factors.

Guideline-Based Evaluation of Patients With Microhematuria

See Fig. 16.1 for the evaluation algorithm of MH from the most recent AUA guidelines (Davis et al., 2012; https://www.auanet.org/guidelines/asymptomatic-microhematuria-(2012-reviewed-for-currency-2016)) and Table 16.1 for other organizational recommendations. Importantly, the AUA guidelines recommend that **patients meeting criteria for evaluation undergo a complete evaluation, even if one phase of the evaluation shows a suspected cause for the MH.** For example, a patient found to have a kidney tumor or stone disease during initial workup of MH should still undergo cystoscopy for clearance of bladder and urethral pathological processes.



+AMH
(≥3 RBCs/HPF on UA with microscopy)
History and physical assessment for other potential AMH causes
(e.g., infection, menstruation, recent urologic procedures)
+
Repeat UA after treatment of other cause(s).
−
Release from care
+
−
Concurrent nephrologic workup if proteinuria, red cell morphology, or other signs indicate nephrologic causes
Renal function testing
Cystoscopy
Imaging (CTU)
If unable to undergo CTU, less optimal imaging options include:
- MR urogram
- Retrograde pyelograms in combination with noncontrast CT, MRI, or US
+
Treatment
−
Follow up with at least one UA/micro yearly for at least 2 years.
+
Follow persistent MH with annual UA. Consider nephrologic evaluation. Repeat anatomic evaluation within 3 to 5 years* or sooner, if clinically indicated.
Follow up as indicated by diagnosis. Re-evaluate for MH after resolution of identified condition.
−
Release from care
*The threshold for re-evaluation should take into account patient risk factors for urologic pathological conditions such as malignancy.

FIG. 16.1 American Urological Association guideline algorithm for evaluation of adult patients with asymptomatic microhematuria. *AMH,*

Asymptomatic microhematuria; *CT,* computed tomography; *CTU,* computed tomography urogram; *HPF,* high-power field; *MH,* microhematuria; *MR,* magnetic resonance; *MRI,* magnetic resonance imaging; *RBC,* red blood cell; *UA,* urinalysis; *US,* ultrasound. (From the American Urological Association.)

The evaluation of an appropriately selected patient with MH begins with a thorough history and physical examination. Specifically, the goal should be to identify causes that would warrant variation from the standard evaluation, such as infection, menstruation, recent vigorous exercise, known medical renal disease, acute viral illness, trauma, and the presence of foreign bodies in the urinary tract or recent urologic instrumentation. The history also should include an assessment of associated symptoms, such as GH, voiding symptoms, or flank pain. Patients' risk factors for known causes of hematuria also should be queried. It is important to know the patient's urologic history, particularly any surgeries or febrile UTIs. It is also critical to ask about the patient's general medical history to identify potentially contributory diagnoses, such as hypertension, renal insufficiency, bleeding disorders, or sickle cell disease. Current medication use, including anticoagulants and antiplatelet therapies, should be elicited, along with recent coagulation values and any concomitant medications that would potentiate the effects of blood thinners. Family history of nephritis, polycystic kidneys, and rare familial tumor syndromes of the kidney (e.g., von Hippel-Lindau syndrome) or urothelium (e.g., Lynch syndrome) also may be informative. In addition, the possibility of finding a tobacco-related illness, such as bladder cancer, makes this a potential "teachable moment" for tobacco users (Bassett et al., 2012; Fiore and Baker, 2013). Thus smoking cessation counseling should be a standard component of the hematuria evaluation discussion for current smokers.

Physical examination should focus on the genitourinary system (e.g., flank tenderness; masses in the flank, abdomen, suprapubic area, or urethra; and enlarged, nodular, tender, or fluctuant prostate.) Physical examination also may identify signs of coagulopathy (bruising), infection (fever), or renal disease (hypertension, edema). If urethral stricture or benign prostatic hyperplasia (BPH) is suspected, a urine flow rate and postvoid residual measurement may be helpful as well.

Laboratory testing includes urinalysis (if not performed previously) to confirm the presence of hematuria and check for dysmorphic red cells, cellular casts, or proteinuria; urine culture if the urinalysis or clinical presentation suggests infection; renal function testing (serum creatinine) to determine whether concomitant nephrologic evaluation is indicated and to guide the selection of appropriate upper tract imaging; and prostate-specific antigen in the appropriate setting.

If a benign cause of hematuria is discovered during the initial history and physical examination (e.g., UTI), that cause should be verified and treated and then the urine should be retested to ensure that the hematuria has resolved in the absence of the presumed benign cause. Moreover, **if a medical renal cause of hematuria is suspected based on the presence of renal insufficiency, hypertension, or abnormalities on urinalysis, nephrology evaluation is recommended, but the patient should still undergo urologic evaluation.**

Cystoscopy in the Diagnostic Evaluation of Hematuria

Cystoscopy is a key component of the hematuria evaluation because it is the most reliable way to evaluate the bladder for the presence of bladder cancer and provides the opportunity to evaluate the urethra. The AUA guidelines indicate that **cystoscopy should be performed in all adults who meet criteria for hematuria evaluation who are 35 years of age or older and/or have risk factors for malignancy.** Bladder cancer is rare (<1 per 100,000) among persons 35 years old or younger (National Cancer Institute, 2018; van der Molen and Hovius, 2012). Among 3762 individuals with asymptomatic MH from 17 screening studies, 98 (2.6%) were diagnosed with a urinary tract malignancy, of whom 95 (97%) were older than 35 years of age. For these reasons, the AUA guidelines state that **cystoscopy may be omitted in persons younger than age 35 years without risk factors or clinical suspicion for bladder cancer** or urethral pathology (see Box 16.1). Again, other organizational guidelines differ slightly in criteria for cystoscopy (see Table 16.1). Potential risks of the procedure include discomfort, injury to the urethra, infection, and the need for additional procedures such as biopsy.

Blue-light cystoscopy using 5-aminolevulinic acid (ALA) or hexyl-aminolevulinate (HAL) instillation is approved by the US Food and Drug Administration (FDA) for evaluation of patients with suspicion of papillary bladder cancer, but the studies supporting its use have been conducted in patients with known bladder cancer, thereby limiting generalizability to MH patients (Davis et al., 2012; Malmstrom et al., 2012). In light of the small incremental risk associated with ALA or HAL and blue-light cystoscopy (rare anaphylactoid shock, hypersensitivity, pain, cystitis, dysuria, hematuria) and the risk for unnecessary biopsies compared with conventional white light cystoscopy, the **AUA guideline recommends against using blue-light cystoscopy for evaluation of MH** (Davis et al., 2012).

Upper Tract Imaging in the Diagnostic Evaluation of Hematuria

Multiphasic computed tomography (CT) urogram (i.e., CT with precontrast, nephrographic, and excretory series) is the imaging study recommended by the AUA guidelines for the evaluation of asymptomatic MH (Davis et al., 2012). CT urography offers complete imaging of the urinary tract and has the highest sensitivity and specificity for detecting lesions of the renal parenchyma and the upper tracts (Vikram et al., 2009). Nonetheless, CT urography does carry risks and may not be appropriate for all patients (e.g., pregnancy, iodinated contrast allergy, renal insufficiency). Furthermore, CT urography uses a relatively high radiation dose (20–30 mSv, with considerable variability across centers), which may be associated with a risk of carcinogenesis (Board on Radiation Effects Research, 2006; Mettler et al., 2008; Tsili et al., 2007; Vrtiska et al., 2009). In the setting of a contraindication to CT urogram, magnetic resonance (MR) urogram may be used as the upper tract study. Moreover, for patients with a contraindication to MR imaging (e.g., pacemaker), as well as in the setting of significant renal function compromise (i.e., estimated glomerular filtration rate <30 and when the administration of gadolinium risks nephrogenic systemic fibrosis), renal parenchymal imaging with noncontrast CT or ultrasound, in conjunction with retrograde pyelography to evaluate the calyces, renal pelvis, and ureters, may be most appropriate.

Not surprisingly, given the overall low diagnostic yield of evaluating asymptomatic microscopic hematuria, together with the potential radiation exposure and health system costs of CT urogram, there remain discrepancies among organizational hematuria guidelines regarding imaging recommendations (Lisanti et al., 2014; Rhéaume-Lanoie et al., 2014; see Table 16.1). Interestingly, a recent modeling study evaluated the potential implications of replacing CT urogram with ultrasound and demonstrated that US plus cystoscopy would be more cost effective than other options with nearly the same diagnostic yield as CT urogram plus cystoscopy (Halpern et al., 2017). Nevertheless, such an approach is not risk stratified and importantly has not been prospectively tested.

Urine Cytology and Urinary Biomarkers in the Diagnostic Evaluation of Hematuria

Urine cytologic examination is highly sensitive and specific for the detection of high-grade urothelial carcinoma, but sensitivity decreases significantly for low-grade urothelial carcinoma, resulting in an overall sensitivity of 15.8% to 54.5%, and specificity of 95.0% to 100% for bladder cancer detection (Chahal et al., 2001; Grossman et al., 2005; Miyanaga et al., 1999; Steiner et al., 2008; Zippe et al., 1999). Indeed, in a large study of patients with hematuria, the sensitivity and specificity of positive/suspicious/atypical cytology were 45.4% and 89.5%, respectively (Mishriki et al., 2013).

Meanwhile, although several urine biomarkers have been approved or cleared by the FDA for detection and surveillance of bladder cancer, few studies have been conducted to evaluate these markers in patients with MH who do not have a history of bladder cancer. Available assays include nuclear matrix protein-22 (NMP-22), bladder tumor antigen, fluorescence in situ hybridization (FISH) for abnormalities of chromosomes 3, 7, 17, and 9p21 (UroVysion [Abbott Molecular, Abbott Park, IL]) and immunocytology for carcinoembryonic antigen and mucin glycoproteins (ImmunoCyt [Scimedx, Denville, NJ] and CertNDx [PCLS, Rock Hill, SC]).

NMP-22 offers a potential advantage in management of patients with MH: it is available as a point-of-care test. However, only two studies have focused on the asymptomatic patient with MH, with one finding a high sensitivity (90.9%) and the other in a screening population demonstrating very low sensitivity (6.0%). Specificity was moderate or high in both studies (76.3% and 82.5%, respectively) (Miyanaga et al., 1999; Steiner et al., 2008). Meanwhile, one study assessed FISH testing in patients with asymptomatic MH with a negative cytology and found that sensitivity and specificity may be high for upper tract tumors in this setting (Huang et al., 2012). A separate FISH study in asymptomatic MH patients (albeit without prior negative cytologic findings) showed sensitivity and specificity of 61% and 93%, respectively, for bladder tumors (Steiner et al., 2008). Immunocytology has been tested in the asymptomatic MH setting in one study of 189 patients (Schmitz-Drager et al., 2007). Here, eight bladder tumors were identified, of which seven were identified by the ImmunoCyt test, for a sensitivity of 87%. However, studies in the urothelial carcinoma follow-up setting have found a far more modest sensitivity (68.1%) (Comploj et al., 2013). The multianalyte urine test CertNDx assesses several markers (mutant *FGFR3*, quantified matrix metalloproteinase-2 [MMP-2], and hypermethylation of *TWIST1* and *NID2*). In a population of patients with hematuria (gross and microscopic) 50 years of age or older without diagnosis of bladder cancer, the sensitivity and specificity of this test were noted to be 87.9% and 56.3%, respectively (Karnes et al., 2012). A similar test, looking for methylation of *TWIST1*, *ONECUT2*, and *OTX1*, along with mutation of *FGFR3*, *TERT*, and *HRAS*, shows promising accuracy for detection of bladder cancer, with sensitivity of 93% and specificity of 86% when combined with age in a cohort of patients undergoing cystoscopy for evaluation of hematuria (van Kessel et al., 2017).

Together, because current evidence indicates that none of the available urinary biomarkers, including cytology, appear to be sufficiently sensitive or sufficiently validated to replace cystoscopy or imaging, **these studies are not recommended by most organizations in the initial evaluation of patients with asymptomatic MH** (Davis et al., 2012; Nielsen and Qaseem, 2016; see Table 16.1). However, **cytologic examination may be considered in patients with a negative initial workup in whom urothelial carcinoma is still suspected, as well as in patients with symptomatic MH**.

Natural History of Microhematuria in Patients With a Negative Initial Evaluation

One of the most vexing questions in the management of MH is how to proceed in patients for whom the initial evaluation is negative. MH has been reported to resolve in approximately one-third of these patients over a period of 3 months to several years (Jaffe et al., 2001; McGregor et al., 1998; Yamagata et al., 1996). Nevertheless, these studies contained large proportions of younger patients, many of whom did not undergo a complete workup at any time, raising the possibility of persistent occult urologic disease. In a set of studies in which patients underwent further evaluation for MH after an initial negative evaluation, 41 malignancies were identified among 1475 patients (2.8%). However, the initial evaluations in these series were often incomplete, the follow-up evaluations were variable, and most of the malignancies were found in a study using CT urography in patients who were not evaluated by CT in the first evaluation (Davis et al., 2012).

In the absence of high-quality evidence, the AUA has issued three guidelines statements, based on expert opinion, pertaining to the follow-up of patients with an initial negative workup (Davis et al., 2012). The first two can be summarized as recommending **following up annual urinalysis for 2 years after a complete negative hematuria workup and releasing the patient from care if the urinalyses confirm resolution of hematuria.** The third statement recommends **repeating the hematuria evaluation within 3 to 5 years in cases of persistent or recurrent asymptomatic MH or for development of symptoms or GH**. We would add that **patients with persistent or recurrent MH in the setting of an incomplete initial evaluation should have the evaluation completed or repeated.**

Key Points: Evaluation of Patients With Microhematuria

- Evaluation of adults with microscopic hematuria includes a history and physical examination, renal function testing, and upper tract imaging for all patients.
- White light cystoscopy is recommended in the evaluation of asymptomatic MH for patients 35 years of age or older and/or those with risk factors for malignancy.
- CT urogram is the preferred imaging modality for the evaluation of hematuria.
- Urine cytologic examination and biomarkers are not indicated in the initial evaluation of asymptomatic MH.
- Patients with a negative complete evaluation can be released from care if subsequent urinalyses confirm resolution of MH. Re-evaluation should be considered in patients with persistent/recurrent MH and in those with an incomplete initial evaluation.

Symptomatic Microscopic Hematuria

The differential diagnosis for symptomatic MH is equivalent to that for patients with asymptomatic MH. However, the risk for malignancy may be significantly higher than in asymptomatic MH (10.5% vs. 5.0% or less) (Shephard et al., 2012; Sultana et al., 1996). In the setting of a symptomatic, culture-documented urinary infection presenting with hematuria, with documentation of hematuria resolution after treatment, a complete workup can be avoided. Because the presence of symptomatic hematuria has been linked to an increased risk for malignancy, current AUA guidelines include several slight modifications to the recommendations for evaluation. Specifically, **cystoscopy is recommended in such patients regardless of age** (Davis et al., 2012). Moreover, although routine cytology is not recommended as part of the routine evaluation for the asymptomatic patient with microscopic hematuria, **cytologic examination is considered an option in the setting of irritative voiding symptoms,** although cystoscopy should not be omitted even if the cytologic findings are negative (Davis et al., 2012).

Gross Hematuria

The differential diagnosis for GH remains the same as outlined earlier for MH. However, **as the degree of hematuria increases, so does the likelihood of finding clinically significant lesions during evaluation** (Mariani, 1989). Specifically, among patients with GH, 50% have been found to have a demonstrable cause, and 20% to 25% have been found to have a urologic malignancy, most commonly bladder cancer and kidney cancer (Alishahi et al., 2002; Edwards et al., 2006; Khadra et al., 2000; Lee and Davis, 1953).

Given the increased frequency with which clinically significant findings are associated with GH, the recommended evaluation in this setting is relatively uniform. That is, **patients presenting with GH in the absence of antecedent trauma or culture-documented UTI should be evaluated with a urine cytologic examination, cystoscopy, and upper tract imaging, preferably CT urogram.** Meanwhile, patients with GH in the setting of a culture-documented UTI should have the infection treated and then a follow-up urinalysis obtained to ensure clearance of the hematuria. The initial assessment for patients presenting with GH should include the history, physical examination, and laboratory studies recommended for patients with MH. Further, patients with GH must be assessed for hemodynamic stability with careful attention to vital signs, anemia with a complete blood count, and, for patients on anticoagulation, coagulation parameters to ensure that levels are within the therapeutic range. After initial stabilization, diagnostic evaluation should then proceed, with cause-specific management as outlined below.

Although clear recommendations are lacking for the follow-up of patients with GH who are found to have a nondiagnostic initial evaluation, the follow-up schedule as outlined for patients with asymptomatic MH may be used as a reference, with consideration given for a full repeat evaluation if episodes of GH recur.

Hemorrhagic Cystitis

Intractable hematuria localizing to the bladder, or hemorrhagic cystitis, may range in severity from a transient condition that quickly resolves after conservative management to a life-threatening condition requiring urgent intervention. Unfortunately, patients in this situation are often elderly and infirm, with medical comorbidities that complicate plans for care.

Hemorrhagic cystitis is characterized by diffuse inflammation and bleeding from the bladder mucosa (Rastinehad et al., 2007). Numerous causes for this condition have been described (Box 16.2), a few of which merit particular mention here. Bacterial infections, for example, are a common cause of GH, with symptomatic resolution typically noted after appropriate treatment. Meanwhile, viral-induced hemorrhagic cystitis may affect children and immunosuppressed adults particularly (e.g., after renal or bone marrow transplantation). **BK virus, a member of the polyomavirus family, is the most common virus associated with hemorrhagic cystitis** (Gorczynska et al., 2005), and adenovirus, particularly types 11 and 35, has been correlated with hemorrhagic cystitis in children and renal transplant patients (Hofland et al., 2004; Lee et al., 1996). Treatment for viral hemorrhagic cystitis is primarily supportive, with hydration, diuresis, and bladder irrigation, although case reports of success with antiviral therapy exist (Rastinehad et al., 2007).

Box 16.2

Differential Diagnosis for Hemorrhagic Cystitis[a]

- Infectious
    - Bacterial
    - Viral (especially BK virus, adenovirus)
    - Fungal
    - Parasitic
- Trauma
    - External
    - Postsurgical (e.g., transurethral resection of the bladder)
- Malignancy

    - Bladder primary
    - Bladder invasion from local/distant primary
- Vascular malformation
- Chemical exposure
    - Cyclophosphamide
    - Ifosfamide
    - Busulfan
    - Thiotepa
    - Temozolomide
    - Aniline dye
    - Ether
    - Nonoxynol-9 (accidental urethral insertion of vaginal contraceptive)
- Radiation therapy history (e.g., prostate cancer, cervical cancer)
- Medication induced
    - Penicillin and derivatives (via immune reaction)
    - Bleomycin
    - Danazol
    - Allopurinol
    - Methenamine mandelate
    - Acetic acid
- Manifestation of systemic disease
    - Amyloidosis
    - Rheumatoid arthritis
- Crohn disease

---

[a] Bleeding localized to bladder after diagnostic workup for gross hematuria with cystoscopy, urine cytology, and upper tract imaging is without clear cause of alternative bleeding source.

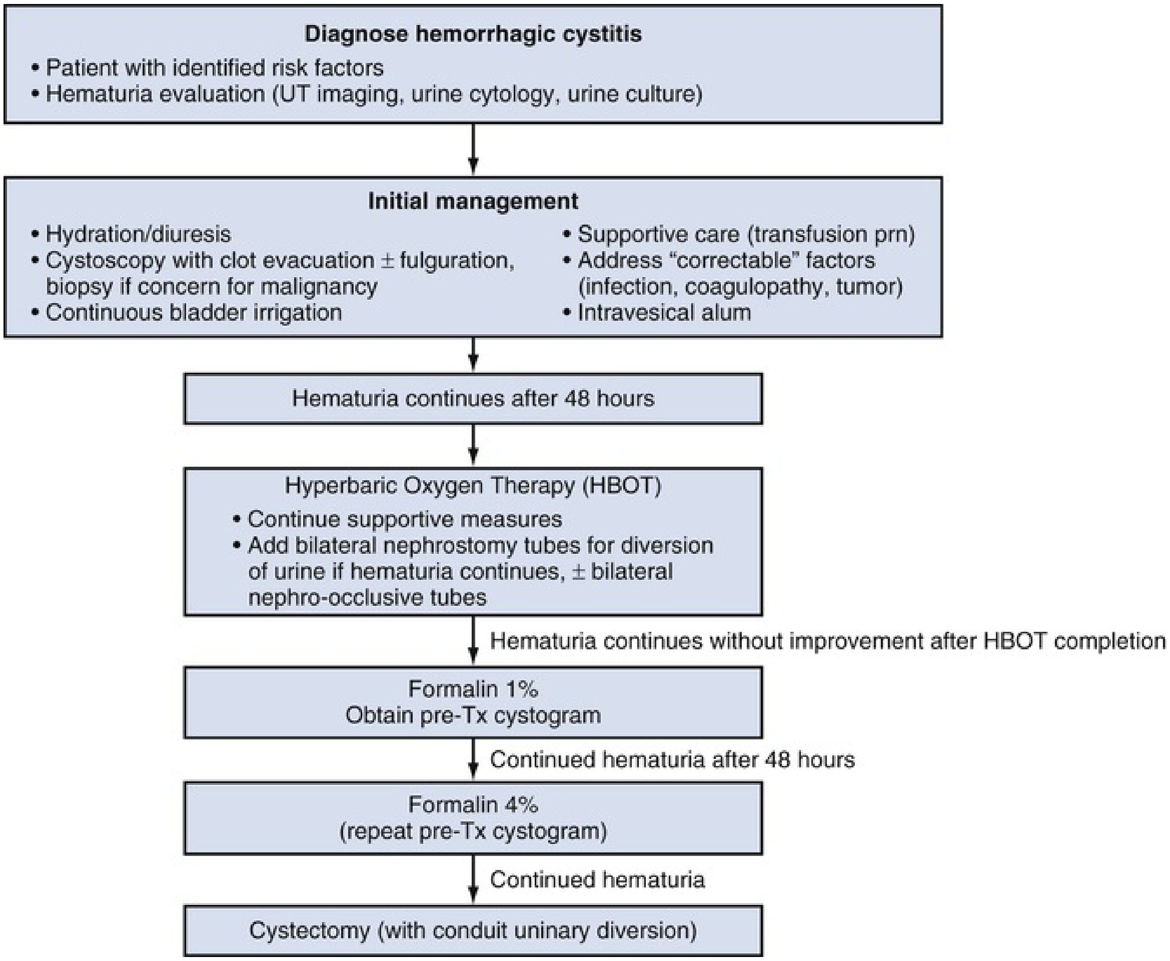
Hemorrhagic cystitis also may result from exposure to the oxazaphosphorine class of chemotherapeutic agents, specifically cyclophosphamide and ifosfamide. Indeed, hemorrhagic cystitis has been reported to occur in 2% to 40% of patients treated with cyclophosphamide (Rastinehad et al., 2007) and is dose dependent. **Bladder toxicity results from renal excretion of the metabolite acrolein, which is produced by the liver and stimulates bladder mucosal sloughing and subsequent tissue**

edema/fibrosis (O'Reilly et al., 2002). The onset of hematuria is typically within 48 hours of treatment (Cox, 1979; Stillwell and Benson, 1988). **2-Mercaptoethane sulfonate (mesna), which binds to acrolein and renders it inert, has been suggested for prophylaxis against cyclophosphamide-induced hemorrhagic cystitis** (O'Reilly et al., 2002). Nevertheless, 10% to 40% of patients will develop the condition despite preventive treatment (Shepherd et al., 1991). Debate continues as to whether mesna is more effective at preventing hemorrhagic cystitis than hyperhydration with forced diuresis and/or continuous bladder irrigation (Shepherd et al., 1991; Vose et al., 1993).

Meanwhile, **radiation therapy for pelvic malignancy represents another predisposing factor to hemorrhagic cystitis.** Indeed, moderate to severe hematuria has been reported in approximately 5% of patients after pelvic radiotherapy, depending in part on factors such as the radiation dosage and mode of delivery, with onset between 6 months and 10 years after treatment (Corman et al., 2003; Smit and Heyns, 2010). Mechanistically, radiation damages the vascular endothelium, thereby inducing subsequent inflammation, fibrosis, and ischemia, with tissue necrosis and mucosal sloughing occurring through progressive obliterative endarteritis (Bevers et al., 1995; Chong et al., 2005; Hader et al., 1993). In the setting of such local vascular compromise, moreover, secondary infection frequently ensues, further compromising tissue healing (Del Pizzo et al., 1998). Importantly, receipt of both cyclophosphamide chemotherapy and pelvic radiation (Wallis et al., 2016) represents risk factors for bladder cancer, and as such, patients presenting with hematuria who have a history of such treatment should be evaluated for bladder cancer before the diagnosis of hemorrhagic cystitis is assigned.

Management of Hemorrhagic Cystitis

The management of hemorrhagic cystitis may occasionally be guided by the particular cause for the condition (e.g., treatment of infection). However, in most cases no cause-directed therapy can be offered, and instead, a sequential approach, depending on the severity of the condition, should be undertaken (Fig. 16.2). Supportive management in the form of increasing urine output via hydration/diuresis, catheter placement with continuous bladder irrigation, and transfusion as needed represent the mainstay of first-line therapy and typically suffice for mild cases. If hematuria continues and/or clotting of the urine cannot be controlled with bladder irrigation, cystoscopy under anesthesia with clot evacuation and fulguration of discrete bleeding sites, as well as biopsy of any areas suspicious for malignancy, is then recommended.



Diagnose hemorrhagic cystitis
• Patient with identified risk factors
• Hematuria evaluation (UT imaging, urine cytology, urine culture)
Initial management
• Hydration/diuresis
• Cystoscopy with clot evacuation ± fulguration, biopsy if concern for malignancy
• Continuous bladder irrigation
• Supportive care (transfusion prn)
• Address "correctable" factors (infection, coagulopathy, tumor)
• Intravesical alum
Hematuria continues after 48 hours
Hyperbaric Oxygen Therapy (HBOT)
• Continue supportive measures
• Add bilateral nephrostomy tubes for diversion of urine if hematuria continues, ± bilateral nephro-occlusive tubes
Hematuria continues without improvement after HBOT completion
Formalin 1%
Obtain pre-Tx cystogram
Continued hematuria after 48 hours
Formalin 4%
(repeat pre-Tx cystogram)
Continued hematuria
Cystectomy (with conduit uninary diversion)

FIG. 16.2 Management algorithm for patients with hemorrhagic cystitis. *prn,* As needed; *Tx,* treatment; *UT,* upper tract.

For hematuria that persists despite such conservative measures, various agents have been investigated for bleeding control. Importantly, there is a lack of large, prospective trials reporting comparative treatment efficacy and safety. Nevertheless, an overview of these measures is warranted to facilitate a systematic approach to management. For one, alum (aluminum ammonium sulfate or aluminum potassium sulfate) may be dissolved in sterile water (50 g alum in a 5-L bag of sterile water [1% alum solution]) and then used to irrigate the bladder at a rate of 200 to 300 mL/h. Through its action as an astringent at sites of bleeding, **alum may cause protein precipitation on the urothelial lining** (Ostroff and Chenault, 1982) **and thereby stimulate vasoconstriction**

and a decrease in capillary permeability (Choong et al., 2000)**. In small series, widely variable success rates (e.g., 45% to 100%), with limited durability of hematuria control, have been reported after alum instillation** (Abt et al., 2013; Choong et al., 2000; Westerman et al., 2016). Although cell penetration and therefore overall toxicity of this agent are low (consisting mainly of suprapubic discomfort and bladder spasms), **systemic absorption may nevertheless occur and may result in aluminum toxicity, with consequent mental status changes, particularly among patients with renal insufficiency.** However, alum may be instilled without anesthesia and has overall relatively favorable efficacy and safety profiles. Thus **this agent may be considered for first-line intravesical therapy among patients with hemorrhagic cystitis failing initial supportive measures, particularly among those without renal insufficiency.**

Although several alternatives exist for initial intravesical instillation therapy options, the collective data to support use are limited by small sample sizes, short-term follow-up, and varied definitions of treatment success. For example, prostaglandins (e.g., carboprost tromethamine [prostaglandin F2-α, PGF2-α]) (Abt et al., 2013) have been used intravesically for hemorrhagic cystitis, and although the precise mechanism of activity remains unclear, these agents are thought to cause vasoconstriction, platelet aggregation, and cytoprotection via mucous barrier regulation (Choong et al., 2000; Abt et al., 2013). Response rates of 50% to 60% have been noted (Choong et al., 2000; Abt et al., 2013), and in fact in a small (19 patients) prospective randomized study, no significant difference in efficacy was noted between PGF2 and alum (Praveen et al., 1992). Notably, however, difficulties with PGF2 access, storage, and high costs have limited generalized utility (Abt et al., 2013). As a defect in the bladder's glycosaminoglycan layer has been thought to contribute to the pathogenesis of hemorrhagic cystitis (Bassi et al., 2011; Payne et al., 2013), intravesical sodium hyaluronate has been used in this setting with noted symptomatic improvement (Payne et al., 2013; Shao et al., 2012). Alternatively, silver nitrate may be instilled into the bladder, resulting in chemical coagulation at bleeding sites. A 0.5% to 1% solution is instilled for 10 to 20 minutes (Rastinehad et al., 2007). The potential for precipitation and upper tract obstruction with this agent led to the recommendation for a cystogram to rule out reflux before administration (Rastinehad et al., 2007).

Aminocaproic acid represents another intravesical treatment alternative. A lysine analogue, aminocaproic acid is a competitive inhibitor of activators of plasminogen, including urokinase, and thus interrupts fibrinolysis and the cascade that perpetuates hemorrhage (Abt et al., 2013; Garber and Wein, 1989; Stefanini et al., 1990). **Continuous bladder irrigation with 200 mg aminocaproic acid/L of 0.9% normal saline has been described, with irrigation continued for 24 hours after hematuria resolves.** Symptom resolution has been reported in up to 92% of patients (Singh and Laungani, 1992). The risk for thromboembolic events may be increased with this treatment, and, importantly, aminocaproic acid must be given only after the bladder has been rendered clot free, because the agent will otherwise lead to the formation of hard clots difficult to eradicate from the bladder (Rastinehad et al., 2007).

Management for patients in whom hematuria remains refractory to the aforementioned measures is particularly challenging and is often guided by the patients' clinical status. That is, for clinically stable patients, **particularly with hemorrhagic cystitis resulting from radiation therapy or cyclophosphamide treatment** (Bratsas et al., 2004)**, hyperbaric oxygen therapy (HBOT) represents an option for the next step in management.** HBOT is carried out in a specially designed chamber and involves administration of 100% oxygen at a pressure of 2 to 3 atmospheres for approximately 90 minutes in 30 to 40 sessions (Bevers et al., 1995; Del Pizzo et al., 1998; O'Reilly et al., 2002). With this, local tissue oxygen tension increases and thus oxygen extraction by tissues increases, thereby diminishing edema and promoting neovascularization, all of which are critical steps in the wound healing process (Hader et al., 1993). Response rates to HBOT of 80% to 90% have been reported (Bevers et al., 1995; Corman et al., 2003; Chong et al., 2005; Mougin et al., 2016; O'Reilly et al., 2002) and have been maintained up to 2½ years after treatment (Weiss et al., 1994). However, with longer follow-up, most patients become symptomatic again, such that the 5-year complete response rate has been noted to be only 27% (Del Pizzo et al., 1998). Reported complications include claustrophobia (20%), otalgia (17%), and, rarely, seizures (O'Reilly et al., 2002). For patients with continued bleeding during therapy, consideration may be given as well to performing bilateral nephrostomy tube insertion, with or without occlusion of the ureters (Gonzalez et al., 2001), to decrease exposure of the hemorrhagic bladder to urokinase and thereby theoretically facilitate hemostasis (Rastinehad et al., 2007), particularly during the relatively prolonged time course of HBOT.

When hematuria persists despite the aforementioned measures, treatment escalation is warranted. In these cases, intravesical **formalin, a solution of formaldehyde that induces cellular protein precipitation and capillary**

occlusion (Choong et al., 2000)**, may be used**. Control of bleeding has been reported in 80% to 90% of cases with formalin (Choong et al., 2000; Ziegelmann et al., 2017), which are relatively higher rates than what has been noted with other intravesical treatments. However, because formalin instillation may induce significant pain, administration under general or spinal anesthesia is recommended. Moreover, intravesical **formalin therapy is associated with significant complications, including bladder fibrosis with associated decreased bladder capacity and ureteral stricturing with proximal hydronephrosis/renal injury** (Abt et al., 2013; Choong et al., 2000). Thus **pretreatment cystogram is recommended to exclude the presence of vesicoureteral reflux and/or bladder perforation** (Donahue and Frank, 1989), and patients must be counseled regarding the potential impact on subsequent bladder function. If reflux is documented, placement of occlusive ureteral catheters is recommended to limit upper tract exposure to the medication. Regardless, moreover, low concentrations of formalin (1% to 4%) should be used, because complication rates (albeit efficacy rates as well) have been linked to dosage (Donahue and Frank, 1989). Instillation (with volumes up to 300 mL or to bladder capacity) (Choong et al., 2000) should be done under gravity, with the catheter no more than 15 cm above the pubic symphysis. Instillation should be limited to 10 to 15 minutes and should be performed with the catheter on light traction to prevent urethral exposure, with care taken to protect all external areas of skin from exposure. Given the potential toxicities of formalin, together with the requirement for administration under anesthesia, this agent should be reserved for second-line therapy.

For clinically unstable patients, as well as for patients with continued intractable bleeding, **internal iliac artery angioembolization represents a potential next step** in management. As reported in 1974 (Hald and Mygind, 1974), angioembolization may be performed unilaterally or bilaterally, even in debilitated patients, with relatively limited risk (Ward et al., 2003). Selective embolization of the anterior branch of the internal iliac artery bilaterally is typically required to achieve hemostasis and may use any of a variety of embolic materials, including gelatin microspheres, polyvinyl alcohol particles, or coils (Loffroy et al., 2014). Care should be taken to avoid embolization of the posterior branch of the internal iliac artery, which, because of subsequent occlusion of the superior gluteal artery, may result in significant gluteal pain. Although initial hemorrhage control after selective angioembolization has been reported in 90% of patients from reported series, the durability of response has not been well established (Delgal et al., 2010). Importantly, moreover, the majority of studies have involved limited numbers of patients and have included heterogeneous clinical situations, including patients with pelvic tumors (Loffroy et al., 2014). As such, the reliability of this approach for patients with hemorrhagic cystitis, particularly, for example, after radiation therapy in which mucosal ischemia underlies the pathophysiology, remains uncertain.

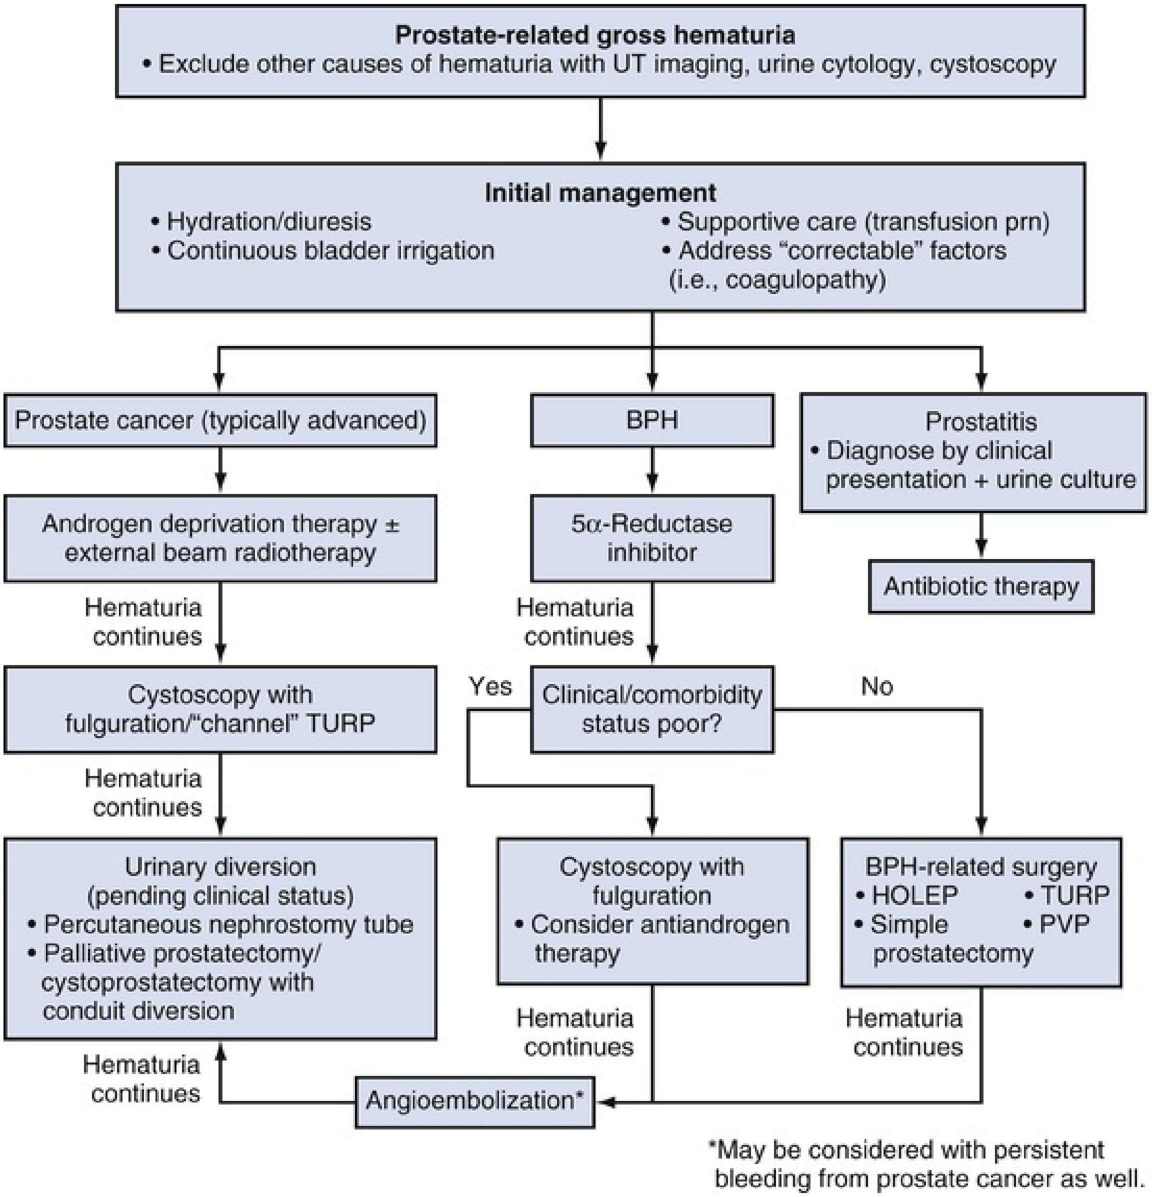
In the setting of failed angioembolization and other conservative approaches, **cystectomy with urinary diversion may be necessary to control bleeding.** Although supravesical urinary diversion alone (e.g., ileal conduit) without cystectomy has been described, complications have been reported in up to 80% of patients with a retained bladder, specifically infection (pyocystis), with rehospitalization in 43% (Eigner and Freiha, 1990; Fazili et al., 2006), suggesting that cystectomy should be performed at the time of urinary diversion if feasible. Unfortunately, such patients are typically elderly, infirm, often significantly deconditioned from the prolonged sequence of bleeding and various therapies, and therefore in poor condition for surgery. As a result, perioperative complication rates have been noted to be significantly higher than what has been reported after cystectomy for bladder cancer (Linder et al., 2014). Therefore, as the clinical course for these patients unfolds, it remains critical for practitioners to carefully balance the risks and benefits of treatment alternatives with the potential for contributing to further deconditioning by extending the course of care.

Key Points: Hemorrhagic Cystitis

- Oxazaphosphorine chemotherapeutic agents have been linked to the development of hemorrhagic cystitis through exposure of the metabolite acrolein to the urothelium.
- Alum may be used as a first-line intravesical therapy for hemorrhagic cystitis in patients without renal dysfunction.
- Formalin is a highly effective form of intravesical therapy for hemorrhagic cystitis. A cystogram should be obtained before therapy to ensure no vesicoureteral reflux.
- HBOT has been associated with response rates of 80% to 100% for patients with hemorrhagic cystitis.

Hematuria From Prostatic Origin

As with hemorrhagic cystitis, hematuria from prostatic origin is a diagnosis made after a complete GH evaluation (including cytology, upper tract imaging, and cystoscopy) to confirm that no other source of hematuria exists. Varied causes exist for prostate-related hematuria, and the severity of such bleeding likewise may range from transient self-limiting episodes to continuous bleeding resulting in the obstruction of urinary flow and in transfusion dependence. Most commonly, prostate-related bleeding is due to BPH, prostate-related infection (prostatitis), or prostate cancer (Fig. 16.3).



Prostate-related gross hematuria
• Exclude other causes of hematuria with UT imaging, urine cytology, cystoscopy
Initial management
• Hydration/diuresis
• Continuous bladder irrigation
• Supportive care (transfusion prn)
• Address "correctable" factors (i.e., coagulopathy)
Prostate cancer (typically advanced)
BPH
Prostatitis
• Diagnose by clinical presentation + urine culture
Androgen deprivation therapy ± external beam radiotherapy
5α-Reductase inhibitor
Antibiotic therapy
Hematuria continues
Hematuria continues
Cystoscopy with fulguration/"channel" TURP
Yes
Clinical/comorbidity status poor?
No
Hematuria continues
Urinary diversion (pending clinical status)
• Percutaneous nephrostomy tube
• Palliative prostatectomy/ cystoprostatectomy with conduit diversion
Cystoscopy with fulguration
• Consider antiandrogen therapy
BPH-related surgery
• HOLEP
• TURP
• Simple prostatectomy
• PVP
Hematuria continues
Hematuria continues
Hematuria continues
Angioembolization*
*May be considered with persistent bleeding from prostate cancer as well.

FIG. 16.3 Management algorithm for patients with persistent hematuria of prostate origin. *BPH,* Benign prostatic hyperplasia; *HOLEP,* holmium laser enucleation of the prostate; *prn,* as needed; *PVP,* photovaporization of the prostate; *TURP,* transurethral resection of the prostate; *UT,* upper tract.

BPH represents the most common cause of prostate-related bleeding and has been cited as the most common cause of GH in men older than 60 (Borth and Nickel, 2006). In fact, BPH has been reported to be the only pathological condition identified in approximately 20% of cases from hematuria studies (Hasan et al., 1994; Lynch et al., 1994). **The cause for BPH-related hematuria has been thought to be increased prostatic vascularity resulting from higher microvessel density in hyperplastic prostate tissue** (Borth and Nickel, 2006;

Deering et al., 1995; Foley et al., 2000; Pareek et al., 2003). This **noted increase in microvessel density has in turn been linked to higher levels of vascular endothelial growth factor (VEGF)** (Borth and Nickel, 2006; Pareek et al., 2003; Walsh et al., 2002).

Frequently, BPH-related hematuria episodes are mild and self-limiting, so once the diagnosis has been established, expectant management with encouraged hydration can be undertaken. Interestingly, although GH has historically been considered an indication for surgery in the setting of BPH, increased understanding of the molecular pathway contributing to the pathophysiologic process (i.e., increased VEGF) has translated into the incorporation of what may be considered targeted medical therapy in the management of patients with BPH-related hematuria.

Specifically, because the pathophysiology of BPH-related bleeding has been postulated as increased cell proliferation stimulating increased vascularity, efforts to suppress prostate growth via androgen ablation have been explored (Foley et al., 2000; Marshall and Narayan, 1993). Estrogens and antiandrogens have, in small case reports, been associated with decreased prostate bleeding, presumably through the repression of androgen-stimulated angiogenesis and the induction of programmed cell death within the prostate (Marshall and Narayan, 1993; Rittmaster et al., 1996). In particular, finasteride, a 5α-reductase inhibitor that blocks conversion of testosterone to dihydrotestosterone and is a treatment for prostate-related outlet obstructive symptoms, has been investigated extensively for BPH-related bleeding. **Treatment with finasteride is associated with decreased VEGF expression** (Pareek et al., 2003)**, prostate microvessel density** (Pareek et al., 2003)**, and prostatic blood flow** (Frauscher et al., 2003)**.**

Clinically, **multiple series have demonstrated efficacy of finasteride for BPH-related hematuria, including in patients being treated with anticoagulation. Symptom improvement or resolution has been consistently noted in approximately 90% of patients** (Carlin et al., 1997; Kearney et al., 2002; Miller and Puchner, 1998; Puchner and Miller, 1995; Sieber et al., 1998). A prospective randomized trial of finasteride versus expectant management in 57 patients with BPH-induced hematuria found that the rate of recurrent hematuria was significantly higher among patients in the control arm (63%) versus finasteride (14%) ($P < 0.05$). Furthermore, 26% of patients in the control arm required surgery for bleeding versus none of the finasteride-treated patients (Foley et al., 2000). The onset of action for finasteride is variable, with improvement in bleeding noted from as short as 2 weeks to up to 9 months after initiating therapy. In addition, a randomized trial of finasteride versus cyproterone acetate versus watchful waiting demonstrated a significant decrease in recurrent hematuria in the finasteride and in the cyproterone acetate cohorts, with no noted difference in efficacy between finasteride and cyproterone acetate in patients treated with this agent (Perimenis et al., 2002). Importantly, similar microvessel density changes and likely BPH-bleeding related sequelae are noted with dutasteride (type I and II 5α-reductase inhibition) (Sugie et al., 2014). Thus, although various forms of hormonal therapy remain options for BPH-related bleeding, the best data to date exist for 5α-reductase inhibition, which likely entails the least side-effect profile. Finally, contemporary studies highlight that, for those patients who eventually require BPH surgery, concurrent therapy with 5α-reductase inhibitors can decrease perioperative bleeding complications and morbidity (Bansal and Arora, 2017; Zhu et al., 2015).

In cases of BPH bleeding in which patients have difficulty with bladder emptying and/or presence of obstructing clot, large-bore catheter placement with irrigation to evacuate all clot material from the bladder should ensue, followed by continuous bladder irrigation until the urine has cleared. If such measures are not sufficient to control bleeding, patients should be taken for endoscopic management under anesthesia, with clot evacuation and electric or laser cauterization. Although the variety of nonspecific intravesical therapies as are used in hemorrhagic cystitis (e.g., aminocaproic acid) have been suggested for use in this setting as well (Borth and Nickel, 2006), limited evidence supports the efficacy of these agents for BPH-related bleeding. Thus **patients with persistent bleeding from BPH despite conservative therapies and/or endoscopic fulguration have traditionally been managed with transurethral resection of the prostate (TURP),** particularly when additional indications for BPH surgery coexist. Although alternative forms of such endoscopic prostate tissue removal/destruction are available (e.g., photoselective vaporization of the prostate, holmium laser enucleation of the prostate) and even suprapubic/retropubic prostatectomy may be undertaken, the principle with all such interventions is to remove the hyperplastic and friable transition-zone prostate tissue. In cases with persistent bleeding despite TURP, selective prostatic artery embolization (PAE), which has been increasingly explored as a treatment for BPH (Feng et al., 2017), is an option for management (Michel et al., 2002). Typically bilateral embolization is performed, here preferably with a superselective approach specifically addressing the prostatic arteries with gelatin microparticles, although selective embolization of the anterior branch of the internal iliac artery has been used as well (Pereira et al., 2016). Initial clinical success has been noted in 90% of patients from angioembolization series, albeit in very small patient numbers and with recurrence in 15% to 28% (Pereira et al., 2016). Although radical prostatectomy or cystoprostatectomy must be considered as well, as with hemorrhagic cystitis, often such patients are poor surgical candidates because of comorbidity status.

Prostatitis, traditionally secondary to bacterial infection, also may result in GH. Indeed, a prior study reported hematuria as the manifesting symptom in 2.5% of men with prostatitis (Rizzo et al., 2003). The mechanism of hematuria in prostatitis is unclear and may be related to inflammation (Borth and Nickel, 2006). Management in this setting should consist of antibiotics when culture-documented bacterial prostatitis is present. Significant recurrent hematuria in the setting of nonbacterial prostatitis is relatively uncommon, and it has been suggested that such cases should be treated with antibiotics in addition to standard supportive measures (Borth and Nickel, 2006).

Meanwhile, **hematuria from prostate cancer typically results in cases of significantly locally advanced tumors,** often with bladder base/trigonal invasion. Indeed, hematuria has been noted to be the most common local symptom among patients with advanced symptomatic prostate cancers (Din et al., 2009). Importantly, the hematuria in these patients, particularly in those who have previously received radiation therapy in the management of their prostate cancer, should be confirmed with endoscopic evaluation to be from a prostate source and not, for example, as a result of hemorrhagic cystitis or secondary bladder malignancy. Unfortunately, these tumors are typically invasive of the bladder and/or pelvic sidewall (T4), and the patients are often elderly and unwell. Thus treatment is primarily with palliative intent. Initial conservative measures, including catheter drainage with or without continuous bladder irrigation, suffice for most cases of mild prostatic bleeding. For patients in whom hematuria is not acutely life threatening, palliative external beam radiotherapy in patients who are radiation naïve with or without androgen deprivation therapy may be administered. Indeed, one series reported that hematuria from advanced prostate cancer responded to palliative radiation in 81% of patients at 6 weeks after treatment; however, durable symptom control was limited: the response rate 7 months after treatment in these patients was only 29% (Din et al., 2009). **Among patients who are not candidates for local therapy, as well as among patients in whom disease has recurred after previous local therapy, androgen deprivation therapy may resolve the hematuria** (Marshall and

Narayan, 1993) **by decreasing prostate vascularity** (Kaya et al., 2005).

In the situation of persistent hematuria with prostate cancer and, in particular, in the setting of bladder outlet obstruction, cystoscopy under anesthesia with fulguration and/or limited, or channel, transurethral resection of prostatic tissue should be undertaken. Moreover, selective angioembolization, as has been reported for severe post-TURP bleeding (Barbieri et al., 2002; Loffroy et al., 2014; Michel et al., 2002; Pereira et al., 2016), may be considered, although data on this approach in the setting of prostatic malignancy are scant and have demonstrated limited durability of bleeding control (Chen et al., 2017). Ultimately, if bleeding persists or escalates, consideration should be given to urinary diversion, which initially may be attempted with percutaneous nephrostomy tube insertion. **With continued prostate hemorrhage, palliative extirpative surgery, which may be in the form of radical prostatectomy but more typically requires cystoprostatectomy and conduit diversion, should be considered, pending patients' clinical and comorbidity status.**

Key Points: Hematuria From Prostatic Origin

- BPH represents the most common cause of GH in men older than 60 years.
- 5α-Reductase inhibitors may be used for BPH-related GH, with potential improvement having been noted within weeks after instituting therapy.
- Androgen deprivation may be effective for patients with locally advanced prostate cancer with GH.
- Angioembolization and/or urinary diversion represent salvage options for management of patients with refractory hematuria pending clinical status.

Urethral Bleeding

Urethral bleeding (urethrorrhagia) is defined as bleeding emanating from the urethra at a point distal to the bladder neck, occurring separate from micturition (Gontero, 2013). A careful history and physical examination may help elucidate whether the source of bleeding is truly from the urethra as opposed to other sites within the lower urinary tract. For example, **blood at the urethral meatus in the absence of volitional micturition, initial hematuria, or blood at the start of urination frequently implies pathological processes distal to the external urinary sphincter.** In women, differentiating urethral bleeding from that of gynecologic origin based on history alone may be challenging, and pelvic examination is typically necessary to clarify the site of origin (Sandhu et al., 2009). Importantly, retrograde urethrogram and cystourethroscopy remain the mainstays for diagnosis in patients with suspected urethral bleeding because direct visualization permits identification of pathological processes in the urethra and biopsy and fulguration allow for histologic characterization and cessation of bleeding.

Causes of urethral bleeding are best classified by gender (Box 16.3). **In men, trauma to the urethral epithelium represents the most common cause of urethral bleeding.** For example, blunt trauma via straddle injury, kick to the perineum, or pelvic fracture often manifests with bleeding and concurrent urinary retention (Mundy and Andrich, 2011). Perineal or penile bruising, accompanied by a hematoma, often is a clear indication of injury related to trauma. **Retrograde urethrography is essential in instances of trauma when a urethral injury is suspected** (Avery and Scheinfeld, 2012; Morey et al., 2014). Meanwhile, a history of foreign body insertion in patients with hematuria may necessitate imaging and/or cystoscopy to ensure no residual foreign elements remain that could perpetuate bleeding or result in subsequent calculus formation (Rahman et al., 2004). **Particular mention should be made to the evaluation of bloody urethral discharge and/or hematuria occurring in patients with a penile fracture. In this setting, prompt evaluation via retrograde urethrography or cystoscopy should be undertaken to evaluate for a urethral injury and to identify the nature and location of the injury before surgical exploration** (Avery and Scheinfeld, 2012; Morey et al., 2014). Evaluation of urethral trauma is covered in Chapter 133.

Box 16.3

Differential Diagnosis for Urethral Bleeding

Male

- Trauma
  - Blunt (straddle injury, kick to perineum)
  - Penetrating (foreign body insertion, failed urethral catheterization, ballistics)
  - Intercourse related (penile fracture, masturbation)
- Urethritis
  - Bacterial (gonococcal, nongonococcal)
  - Viral
  - Chemical (amiodarone induced)
  - Autoimmune (reactive arthritis)
- Malignancy
  - Urothelial carcinoma
  - Squamous cell carcinoma (meatus/glans)
- Condyloma
- Calculus disease

Female

- Trauma
  - Blunt (pelvic fracture)
  - Penetrating (foreign body)
- Urethral diverticulum
- Urethral caruncle
- Urethritis
- Malignancy
- Calculus disease

Urethritis refers to infection or inflammation of the epithelial lining of the urethra and has been reported secondary to bacterial or viral infection, chemical irritants (i.e., spermicidal jelly), medication-related (i.e. amiodarone), and, rarely, autoimmune systemic conditions (human leukocyte antigen B27 [HLA-B27] reactive arthritis) (Brill, 2010). Urethral discharge on palpation may be noted with urethritis in men. Urine microscopy and cultures, as well as urethral swabs for causative organisms, represent essential components of the evaluation.

Urethral tumors are rare, although blood per meatus may be a manifesting sign in patients with urothelial carcinoma, specifically in men who have undergone a radical cystectomy with urethra still in situ (White and Malkowicz, 2010). At the same time, urethral caruncles are benign urethral lesions typically originating from the posterior lip of the urethra, most commonly found in postmenopausal women (Conces et al., 2012). These lesions are thought to arise from prolapse of distal urethra as a consequence of estrogen deficiency. In addition to the classic presentation of dysuria, dyspareunia, and dribbling, women with a urethral diverticulum also may report intermittent episodes of bleeding, and urethral discharge may be noted on examination (Greenwell and Spilotros, 2015).

Hematuria Originating From the Upper Urinary Tract

Hematuria emanating from the upper urinary tract is frequently asymptomatic, although macroscopic bleeding with clots can result in subsequent ureteral obstruction, with patients experiencing “clot colic,” as well as anemia, and even rarely hemodynamic instability (Lano et al., 1979). Most often, hematuria from the upper tract manifests as total hematuria or bleeding throughout the duration of the urinary stream (Mazhari and Kimmel, 2002) and may be characterized by wormlike clots passed via the urethra. A variety of causes can result in bleeding from the upper tract (Box 16.4), with the most common causes of hematuria from the upper urinary tract including stones, trauma, and malignancy. The evaluation and management of these entities is described elsewhere. Here we highlight several particularly salient, albeit less frequent, causes of upper tract hematuria.

Box 16.4

Differential Diagnosis for Upper Urinary Tract Bleeding

- Renal glomerular diseases
  - IgA nephropathy (Berger disease)
  - Thin basement membrane disease
  - Acute glomerulonephritis (e.g., poststreptococcal)
  - Lupus nephritis
  - Hereditary nephritis (e.g., Alport syndrome)
- Renal tubulointerstitial diseases
  - Papillary necrosis
    - Sickle cell nephropathy
    - Analgesic nephropathy
  - Polycystic kidney disease
  - Medullary sponge kidney
- Vasculitis

- Henoch-Schönlein purpura
  - Wegener granulomatosis
- Infection
  - Pyelonephritis
  - Xanthogranulomatous pyelonephritis
  - Renal tuberculosis
  - Fungal infection
- Obstruction
  - Ureteropelvic junction obstruction
  - Ureteral stricture
- Nephrolithiasis
- Malignancy
  - Renal cortical tumors (renal cell carcinoma, benign tumors)
  - Upper tract urothelial carcinoma
- Fibroepithelial polyp
- Vascular diseases
  - Renal arteriovenous malformations (congenital, acquired)
  - Iliac arterioureteral fistula
  - Renal artery aneurysm (especially ruptured)
  - Renal artery pseudoaneurysm
  - Renal artery and/or vein thrombosis
  - Hemangioma
  - Atheroembolic disease (including infarction)
  - Nutcracker syndrome
  - Loin-pain hematuria syndrome
- Trauma
  - Blunt
  - Penetrating
- Lateralizing essential hematuria

Medical Renal Disease

Glomerular diseases are a constellation of acquired or inherited conditions in which the glomeruli are damaged. Consequences include loss of RBCs and protein in the urine, with the clinical sequelae of hematuria, hypoproteinemia with associated edema, and reduced glomerular filtration rate. **Urinary findings suggestive of a glomerular cause include the presence of RBC casts in the**

urinary sediment, dysmorphic RBCs, and proteinuria (Yun et al., 2004).

Meanwhile, tubulointerstitial diseases broadly refer to kidney diseases affecting structures in the kidney outside the glomerulus. For example, **sickle cell nephropathy is associated with sickle cell disease, whereby sickled erythrocytes decrease medullary blood flow, causing local ischemia, microinfarction, and papillary necrosis** (Pham et al., 2000). Analgesic nephropathy can likewise cause renal papillary necrosis and subsequently chronic interstitial nephritis. Percutaneous renal biopsy may be a valuable diagnostic modality in case of a suspicion for glomerular or tubulointerstitial causes of hematuria. Importantly, current guidelines advocate completion of the hematuria evaluation even when medical renal causes are suspected (Davis et al., 2012).

Vascular Conditions Affecting the Urinary Tract

A variety of vascular conditions can cause hematuria. For example, ureteroiliac artery fistula is an uncommon but potentially life-threatening cause of hematuria. **Predisposing factors include pelvic or vascular surgery, pelvic irradiation, extensive ureteral mobilization, and chronic ureteral stenting** (Muraoka et al., 2008). With regard to management, high mortality rates have been reported with surgical repair of ureteroiliac fistulas, and as such **angiographic localization with vascular stenting has become the current preferred management approach** (Keller et al., 1990; Vandersteen et al., 1997). Renal arteriovenous malformations (AVMs), meanwhile, are abnormal communications between intrarenal arterial and venous systems, with congenital and acquired (iatrogenic) causes. **Acquired AVMs account for 75% of such cases and have been associated with renal biopsy, renal surgery (partial nephrectomy, nephrolithotomy), and trauma** (Muraoka et al., 2008). **Arteriography with selective angioembolization is considered the primary diagnostic and therapeutic option for suspected renal AVMs,** affording symptom resolution with maximal preservation of functional renal parenchyma. Thus **expeditious angiography should be considered for patients with a recent history of a renal procedure presenting with GH.** The goal of AVM embolization is occlusion of the site where abnormal arterial and venous communication exists. Renal artery aneurysms, moreover, may be related to connective tissue disorders and are generally asymptomatic. Hypertension may be present in up to 90% of affected persons, and dissecting aneurysms may cause flank pain with GH (Coleman and Stanley, 2015). Renal artery aneurysms and pseudoaneurysms are generally managed initially with blood pressure control and subsequently via endovascular approaches in the refractory albeit hemodynamically stable patient, whereas surgical intervention is typically necessary in the unstable patient (Klausner et al., 2015; Mohan and Stephen, 2013).

"Nutcracker syndrome" (i.e., renal vein entrapment syndrome) is defined as the compression of the left renal vein between the abdominal aorta posteriorly and the superior mesenteric artery anteriorly. Hematuria has been postulated to occur as a result of increase in left renal vein pressure causing small-volume rupture of thin-walled capillaries into the collecting system (Wolfish et al., 1986). Left renal vein transposition, superior mesenteric artery transposition, and nephrectomy have been described as surgical approaches for management of this condition (Hohenfellner et al., 2002). More recently, endovascular stenting to maintain a patent renal vein has been reported as well.

Lateralizing Essential Hematuria and the Evaluation of Upper Urinary Tract Bleeding

Lateralizing essential hematuria, also termed *benign essential hematuria* or *chronic unilateral essential hematuria*, is defined as macroscopic hematuria cystoscopically localized to one side of the urinary system without a clear identifiable cause (Nakada, 2003). As such, patients have typically had normal prior radiographic studies. Although rare, manifestations of lateralizing essential hematuria may range from minimally symptomatic GH to clot retention and anemia (Nakada, 2003). The differential diagnosis for this entity is as noted earlier for upper tract bleeding (see Box 16.4), although in many such cases no identifiable cause can be determined.

Cystoscopy at the time of bleeding may allow lateralization of the source of hematuria. Subsequently, in the absence of a clear cause for bleeding localized to the upper tract in a patient with lateralizing essential hematuria, direct endoscopic inspection with ureteropyeloscopy is recommended as a diagnostic and potentially therapeutic modality (Nakada, 2003). **Critical components of diagnostic ureteropyeloscopy include the judicious use of guidewires (to avoid inadvertent urothelial injury), low-pressure irrigation, and systematic evaluation of all calices from a superior-to-inferior approach** (Ankem and Nakada, 2006). Biopsy samples can be obtained for lesions suspicious for malignancy, and fulguration of such tumors or other noted sources of bleeding (i.e., hemangioma) can be accomplished as well.

Key Points: Urethral Bleeding and Hematuria Originating From the Upper Urinary Tract

- Urethral bleeding should be suspected with blood at the meatus and/or initial hematuria.
- A concern for traumatic urethral injury should prompt retrograde urethrogram.
- Urinary findings suggestive of a glomerular or tubulointerstitial medical renal disease include the presence of RBC casts in the urinary sediment, dysmorphic RBCs, and proteinuria.
- In patients with GH after a recent renal procedure, expeditious angiography should be considered to allow for the diagnosis and management of renal AVM.

Complications of Urologic Surgery

Reza Ghavamian MD, Charbel Chalouhy MD

Like all surgical disciplines, urologic surgery can be associated with a variety of diverse complications. Although the advent of endourology and minimally invasive surgery has played an unprecedented role in minimizing morbidity, it has also introduced newly described and reported periprocedural complicating events. Training in urology has also witnessed another paradigm shift, from the era of classic surgical mentoring to the current use of simulators and virtual reality surgery. Learning curves of complex surgical procedures such as open radical prostatectomy once estimated to be around 100 to 1000 cases have dropped to 40 cases with robotic-assisted surgery. Surprisingly, complication rates have not followed the same trend, and some authors associate this with the increased number of young surgeons progressing through their learning curves. There has been a dramatic increase in the use of minimally invasive procedures in the surgical management of urologic disease. These include the wide range of modern endoscopic and endourologic procedures and the use of laparoscopic and robotic surgical techniques. As such, surgical training has also evolved with a dramatic decrease in the exposure to major open surgery in the average urologic training program. Today, major index and common urologic oncologic and reconstructive procedures are performed in a minimally invasive fashion. Although the new generation of surgeons are better trained in minimally invasive techniques, the principles for the treatment of major complications remains the same. Colombo et al. reported on the single-institution analysis of 1867 laparoscopic procedures. **Of these, the incidence of intraoperative and postoperative complications were 3.5% and 8.9%, respectively, with an associated mortality rate of 0.4%. Increased incidence of complications was associated with several factors, such as procedure complexity (laparoscopic partial nephrectomy and cystectomy), length of surgery greater than 4 hours, and serum creatinine greater than 1.5 mg/dL. Complications decreased with increasing surgeon experience** (Colombo et al., 2007). Several studies have shown that complications increase up to ninefold with procedure complexity and decrease fourfold with surgeon experience. In a study of 2407 procedures, Fahlenkamp et al. reported that as more experience is gained in urologic laparoscopy, the number of complications actually increases as more complex cases are tackled. The complication rate depended on the difficulty of the procedure and averaged 1.0%, 3.9%, and 9.2%, respectively, for easy, difficult, and very difficult operations. In this series, the overall complication rates increased from 4.4% to 16%, conversion rates increased from 0.8% to 5%, and mortality rates were 0.9% (Fahlenkamp et al., 1999). Laparoscopy has the same set of complications as open surgery. However, there is a unique set of complications related to pneumoperitoneum and access, for example. A high index of suspicion is necessary intraoperatively and postoperatively to detect and treat these complications in an expeditious and safe manner. Although technology has changed the actual performance of operations, it has also led to the development of minimally invasive means to treat surgical complications. These include interventional radiologic techniques and, in many instances, minimally invasive laparoscopic and/or robotic approaches to treat complications. Many recently graduated surgeons come to face challenging situations and complications that were not encountered during their training with an obvious lack of specific management guidelines. Robotic simulators of operative complications or animal models might come into play once again to bridge this gap in training.

As expected, there is a wide array of physiologic, medical, and surgical complications associated with different urologic procedures. Complications are even more specific to laparoscopic and minimally invasive surgery, which is being increasingly utilized in urologic practice. Physiologic complications such as arrhythmias, more specifically bradycardia resulting from gas extension of the peritoneum, can occur. Hypercarbia and acidosis caused by CO_2 and ventilatory problems with resultant decrease in respiratory reserve and increase in airway pressure can result. These physiologic effects are discussed elsewhere in this book in the chapters on laparoscopy.

Positioning, access, vascular, urologic, bowel, and visceral complications can occur. As such, procedure-specific complications, especially those associated with endourologic procedures, are not covered here and are addressed elsewhere in this book in the chapters that specifically address each particular procedure. Hence, this chapter will focus on various general complications of common major urologic procedures. It will also attempt to propose strategies to deal with and more importantly to avoid different complex scenarios.

Classification of Complications

The Clavien-Dindo Scale

The Clavien-Dindo grading system is the recommended uniform approach for describing and reporting complications after surgery. The stratification of this system depends on the severity of the complication and the invasiveness of the intervention required to manage it. The utilization of the Clavien-Dindo grading scale has increased over the past several years in urologic practice from 21% in 2010 to 50% in 2012 (Mitrapoulos, 2017, Yoon et al., 2013). This system was not designed for urologic surgery, but its use has been validated, and it has proven to be simple, reproducible, and applicable to our specialty (Rassweiler et al., 2012).

The Clavien-Dindo system is classically based on management of a complication rather than its severity or morbidity. It also does not differentiate between early and late postoperative complications or address intraoperative complication reporting, and it may not be suitable for pediatric urology. Despite this, it is the most commonly used tool and allows for objective reporting of postoperative complications. In fact, the interobserver agreement rate was reported to be as high as 89%, even in nebulous clinical scenarios when it was evaluated a few years after its early use (Clavien et al., 2009; Dindo et al., 2004).

In urology, this grading system has been the subject of procedure-specific assessments. De la Rosette et al. reported on the applicability of the Clavien-Dindo scale to percutaneous nephrolithotomy (PCNL). Specific complications were assigned to the different grade categories in an attempt to standardize this scoring system when reporting adverse outcomes related to PCNL. This study on 4230 patients from the PCNL global study database showed significant concordance among urologists when reporting the more severe complications in higher Clavien-Dindo grades than in lower grades (3 or less), when low interurologist reliability was identified (De la Rosette et al., 2012). This weakness is dependent on the mismatch perception of care providers to the potential risks patients are exposed to versus the actual management and treatments required for a specific complication after PCNL. Many groups have since evaluated the utility of the Clavien-Dindo grading system in different urologic procedures such as laparoscopic or open radical nephrectomy and robotic prostatectomy.

The Clavien classification serves its purpose in evaluating outcomes in academic and teaching centers. Utilizing this scheme, as an instrument in outcomes, there is an 80% observed concordance in surgical outcomes among postgraduate trainees and attending urologists (Elkoushy et al., 2013) (Table 17.1).

TABLE 17.1

The Clavien Dindo Classification[a]

GRADES	DEFINITION
Grade I	Any deviation from the normal postoperative course without the need for pharmacologic treatment or surgical, endoscopic, and radiologic interventions Allowed therapeutic regimens are: drugs as antiemetics, antipyretics, analgesics, diuretics, and electrolytes and physiotherapy. This grade also includes wound infections opened at the bedside.
Grade II	Requiring pharmacologic treatment with drugs other than such allowed for grade I complications. Blood transfusions and total parenteral nutrition are also included.
Grade III	Requiring surgical, endoscopic, or radiologic intervention
Grade IIIa	Intervention not under general anesthesia
Grade IIb	Intervention under general anesthesia
Grade IV	Life-threatening complication (including CNS complications)[b] requiring IC/ICU management
Grade IVa	Single-organ dysfunction (including dialysis)
Grade IVb	Multiorgan dysfunction
Grade V	Death of a patient
Suffix “d”	If the patients suffers from a complication at the time of discharge, the suffix “d” (for “disability”) is added to the respective grade of complication. This label indicates the need for a follow-up to fully evaluate the complication.

[a] The treatment modality used to correct a certain complication remains the cornerstone of this classification. There are seven grades, and some subdivisions of some grades allow pooling of the rare and severe complications.

[b] Brain hemorrhage, ischemic stroke, subarrachnoidal bleeding, but excluding transient ischemic attack (TIA).

CNS, Central nervous system; *IC,* intermediate care; *ICU,* intensive care unit.

Standardization is the cornerstone for reducing errors and avoidable morbidity. In the future, similar to different treatment guidelines, surgeons may have to define procedural guidelines. This will include optimal operational performance including a standardization of all surgical steps and adverse occurrences that can be considered as surgical errors. This would encourage analysis of the individual performance of a surgeon according to intraobserver and interobserver perceived errors. It is evident that grading systems such as the Clavien system are only one correct and necessary step in this direction.

Physiologic Complications

The surgeon should be familiar with physiologic complications such as arrhythmias, more specifically bradycardia resulting from gas extension of the peritoneum, hypercarbia, and acidosis caused by CO_2 and ventilatory problems, with resultant decrease in respiratory reserve and increase in airway pressure.

Positional and Neuromuscular Complications

Neuromuscular complications occur as a result of direct surgical trauma or improper positioning and pressure (Chuang et al., 2011). Positioning for urologic procedures is variable. A variety of positions are employed by the surgeon for adequate access to the target organ. This ranges from the classic supine position to full or modified lateral decubitus positions (flank positions) for renal surgery and modified and full lithotomy positions. Direct compression of specific nerves against the patient's own body, or the operation table is often the mechanism of injury. Obese patients are at increased risk as the weight of the patient's body can be excessive pressure on affected and vulnerable pressure points. These patients are also at risk for extended operating times because of their body habitus (Mendoza et al., 1996). Recently with the advent of robotic surgery, the patient is also positioned in exaggerated and steep Trendelenburg position. The upper and lower extremities are at risk for these “compromised” positions. Colombo et al. reported on a series of 1867 patients who underwent laparoscopic operations for urologic cancer and reported neuromuscular complications at 1% (Colombo et al., 2007). Others have reported an incidence of less than 3% in urologic procedures, although higher rates in the order of 6% have been reported in robotic series (Wolf et al., 2000; Mills et al., 2013). Permanent neurologic impairment is very rare, as spontaneous recovery often results with minor positional trauma. For the sake of discussion, we describe common positional nerve injuries and intraoperative nerve injuries.

Positional Nerve Injury

Positioning injuries are usually the result of compression injury during prolonged operative times with or without adequate padding and support. Insufficient padding and cushioning of pressure points contribute greatly to neuromuscular injuries, especially in obese patients. The clinical presentation is in the immediate postoperative period affecting the area of sensory and motor supply of the damaged nerve. Sensory loss, paresthesias, or motor deficit results depending on the affected nerve territory.

In the lithotomy and modified lithotomy positions, the posterior tibial nerve can be injured as a result of compression of the posterior knee against the stirrups, resulting in weak plantarflexion. This can be associated with sensory loss in the sole and lateral aspect of the foot and posterior calf paresthesia. The peroneal nerve can also can be compressed against the stirrups as it courses laterally around the fibular neck with resultant foot drop and foot eversion weakness. Excess traction of the legs and compression against stirrups are also associated with injuries to the pudendal nerve resulting in variable perineal sensory loss and rarely incontinence. The peroneal nerve is also at risk in the lateral position, as excess pressure on the dependent leg without adequate padding can be the mechanism of injury. Excessive pressure on the leg against the operative table results in ipsilateral foot drop. Although the obturator nerve is most at risk during pelvic surgery, positional injury to this nerve has been described with hyperflexion of the thigh at the hip joint in exaggerated lithotomy positions causing motor weakness in thigh adduction.

Injuries can also occur with supine positioning. **Inadequate cushioning and padding is very often the reason for sciatic nerve injury. Lateral calf and foot numbness usually ensues.** In the upper extremities, surgeons should carefully check for excessive abduction of the arm greater than 90 degrees on the arm board and secure it before prepping and draping the patient as this can be easily missed once patient is covered. Patients can wake up with shoulder pain and arm weakness of variable severity. Early physical therapy may be necessary. **Radial nerve injury can result in wrist drop. It usually occurs when the arm is dislodged off the armrest in supination and not secured properly. When the arm is dislodged in pronation, the median nerve is affected resulting in a weak hand grip and decreased palmar sensation. Ulnar nerve injuries occur with excessive hyperextension of the forearm and pronation, or when the elbow is flexed at 90 degrees with arms folded across the chest. Postoperatively, a weakened grip ensues or a claw hand consisting of extended metacarpophalangeal and flexed interphalangeal joints usually of the fourth and fifth fingers.** Recently with the advent of robotic prostatectomy, the arms are tucked in and affixed to the side of the patient's abdomen. Care must be taken to adequately pad the patient's hands to keep the wrist protected and straight. Also, compression of the ulnar nerve against the patient's torso or the table can result in the same consequences as described earlier. Sciatic nerve injuries can occur from inadequate padding and result in lateral calf and foot numbness.

The brachial plexus can also be at risk in the lateral position when the dependent shoulder or arm is under the rib cage. Symptoms include shoulder pain and arm weakness of variable degrees. **The majority of brachial plexus injuries result from excessive arm abduction (greater than 90 degrees) and external rotation and posterior shoulder displacement.** This can occur in the supine or lateral position. An axillary roll should be placed to protect the brachial plexus during flank positioning.

The lower extremities are the mostly affected in the prone position. Anterior tibial nerve compression can cause foot drop when the affected foot is left in plantarflexion for extended periods. The same mechanism of injury can be seen in the reverse Trendelenburg position because the patient's body weight exerted on the feet induces plantarflexion when adequate support and padding to the sole of the foot is not provided. Another nerve prone to injury in the prone position is the lateral femoral cutaneous nerve. Excessive pressure on the lateral thigh results in numbness in the lateral and anterior thigh.

Operative Nerve Injury

The most encountered nerves during urologic surgeries are the genitofemoral nerve, ilioinguinal, and obturator nerves. During ureteral reimplantation and psoas hitch procedures, postoperative neuropathy resulting from injuries to the genitofemoral, femoral, and lateral cutaneous nerve has been reported in close to 5% of patients (Pini and Leoni, 2011). **The anchoring suture on the psoas tendon can cause genitofemoral nerve entrapment affecting loss of sensation to the scrotum and medial thigh.** Symptoms range from paresthesia to severe pain in the nerve territory, a constellation of symptoms often referred to as *psoas syndrome*. The femoral nerve is also at risk for injury during psoas hitch operations. The thickness of the psoas tendon is variable in patients, and in some the tendon as a discrete entity is quite subtle. Care should be taken as in extremely thin patients the femoral nerve could be mistaken for the psoas tendon. As a matter of principle, longitudinally oriented sutures along the direction of the tendon are less inclined to entrap neural structures than horizontally oriented sutures along the width of the tendon.

The ilioinguinal nerve is at risk during inguinal orchiectomy, and hernia operations are responsible for the majority of ilioinguinal nerve injuries. **The ilioinguinal nerve courses across the anterior abdominal wall and along the inguinal canal to innervate the inguinal region and lateral hemiscrotum.** Symptoms of pain and paresthesia in this territory can result.

Intraoperative obturator nerve injury is a risk factor associated with pelvic lymph node dissection. The obturator nerve is also an important landmark in the lateral dissection during robotic radical cystectomy and must be identified and fully differentiated. With medial displacement of the external iliac vessels and of the nodal packets in the triangle of Marcille, the obturator nerve is exposed along its full length. **The obturator nerve holds important sensory function to the inner thigh and motor supply to the adductor muscles of the inner thigh** (Loeb et al., 2010). Indiscriminate application of clips in this area is ill advised. All clips must be applied with full visualization of the obturator nerve. If clips are applied to the nerve, they must be removed. In case of transection, repair is warranted by approximating the severed ends with 7-0 nonabsorbable sutures. This can be performed in an open fashion or using robotic technique if the ends can be approximated in a tension-free manner. Intensive postoperative physical therapy is initiated as soon as possible. Lower rates of obturator nerve injury have been reported in recent series compared with early experience with minimally invasive surgery (0.1% vs. 5.1%). The proximal portion of the nerve is at the highest risk as it emerges close to the internal iliac vein representing 77.8% of reported cases (Gözen et al., 2015).

Gluteal Compartment Syndrome

Gluteal compartment syndrome is a very rare condition usually associated with trauma and medical conditions, but cases in the literature associated with positioning are reported in obese patients and after prolonged operative times. Early signs include gluteal tenderness and decrease in vibratory sensation on neurologic examination. The thighs and gluteal regions can be swollen and engorged with severe pain on passive stretch (Heyn et al., 2006). Orthopedic consult is warranted whenever the diagnosis is suspected. Compartment pressure measurement and monitoring will dictate the next step in management. Usually, early fasciotomy will prevent severe rhabdomyolysis and spiking increases in creatine kinase as well as concurrent kidney injury. To decrease this risk, surgeons should be mindful of lengthy operative times and should ensure optimal positioning and padding for adequate cushioning, especially in obese patients (Keene et al., 2010).

Lower Extremity Compartment Syndrome

Lower extremity compartment syndrome has been encountered in patients in the lithotomy position, especially in early experience with minimally invasive surgery. Long operative times were associated with more complex cases performed laparoscopically or robotically. Compartment syndrome is attributable to impaired perfusion and decreased lower limb perfusion pressure leading to tissue ischemia and increase in compartmental pressure. The overall incidence of lower extremity compartment syndrome is 1 in 3500 cases, although higher incidences are seen in urology series (Mumtaz et al., 2002). In fact, compartment syndrome has been reported in as high as 1 in 500 cases of radical cystectomies because of prolonged operative times.

Prevention is key, especially in patients who are at risk, such as those with obesity or peripheral vascular disease or those undergoing procedures associated with marked perioperative blood loss. Other risk factors include muscular calves and intraoperative hypotension. Preventive measures include avoiding excessive elevation of the legs in the lithotomy position. Whenever this is needed in long procedures, lowering the limbs every 2 hours is advised. Dorsiflexion of the ankle should be avoided when positioning is completed at the start of the case, and care should be taken to effectively protect pressure points with enough cushioning. Fasciotomy and surgical decompression is warranted when compartment pressure is greater than 30 mmHg in symptomatic patients. When compartment pressure is greater than 50 mmHg for more than 3 to 4 hours, irreversible muscular damage ensues (Simms and Terry, 2005) (Fig. 17.1).

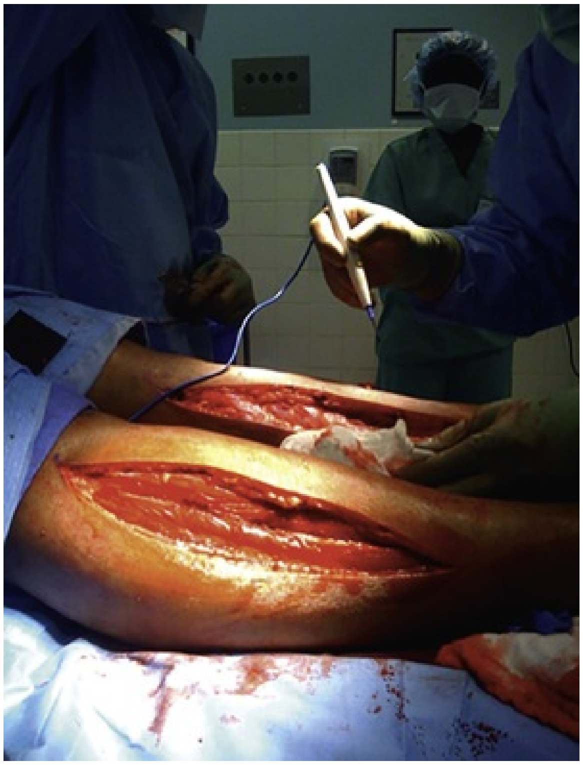

FIG. 17.1 Extended fasciotomies in a patient with bilateral lower extremity compartment syndrome.

Delays in diagnosis can have disastrous consequences. Extreme pain in the lower extremities should raise suspicion as to the presence of lower extremity compartment syndrome. One confounding differential diagnosis is deep venous thrombosis (DVT), but this can be reliably excluded by a lower extremity duplex scan. All staff should be aware of these risk factors to contribute to prevention in lengthy operations or help establish early postoperative diagnosis (Raza et al., 2004).

Urinary Complications

Urine leaks are common complications of urologic surgery. These injuries can happen in both upper tract and lower tract surgery and are specific to the particular operation performed. These include urinary complications in extirpative and reconstructive procedures. Overall, they can lead to significant morbidity and increase in hospital stay. Most common urinary complications occur with both minimally invasive and open techniques, and at times their management is similar. Detection is key, as intraoperative repair and reconstruction can lead to less morbidity and obviate subsequent secondary procedures. Unfortunately not all are detected intraopereatively, and many manifest several days or weeks postoperatively. We will describe common urinary complications as they pertain to upper tract and lower tract urologic procedures.

Urine Leaks After Upper Tract Urologic Surgery

Urine leaks can occur after extirpative and reconstructive upper tract surgery such as partial nephrectomy and pyeloplasty. The ureter can also be injured during various abdominal urologic, gynecologic, and general surgical retroperitoneal operations. For the most part, the principles of diagnosis and management are similar. In this section, we focus on common index urologic procedures and scenarios.

Urine Leaks After Partial Nephrectomy

With increasing experience with robotic partial nephrectomy, there has been a decrease in the reported incidence of urine leaks after partial nephrectomy. The reported incidence of urinary fistulas in series of open partial nephrectomy varies ranging from 0.5% to 21% (Campbell et al., 1994). With the introduction of laparoscopic partial nephrectomy, the specific rate of this complication decreased to 2.4%. This was attributed to a more conservative case selection for the laparoscopic approach, while bigger masses and more endophytic or hilar tumors were being addressed with the open approach and were associated with increased entries in the collecting system (Cacciamani et al., 2018). Currently, robotic partial nephrectomy has matured into a widespread technique, with remarkable precision for reconstruction compared with the open procedure regarding blood loss and associated complications. Some have reported a benefit in the robotic approach compared with the laparoscopic approach regarding ischemia time, positive margins, and renal functional recovery time, (Cacciamani et al., 2018). Although many reviews of the literature attempt to compare the rate of urinoma and other complications among different techniques, none have succeeded in demonstrating a statistical difference (Choi et al., 2015; Xia et al., 2017). In summary, the historical incidence of urine leak ranges from 1.0% to 17.4% for open partial nephrectomy and 1.6% to 16.5% for laparoscopic partial nephrectomy, and the most recent published series of robotic partial nephrectomy experts report rates as low as 0.78%.

Risk Factors and Diagnosis

Urine leaks are the most common complication of partial nephrectomy after hemorrhagic complications. As more complex tumors are tackled, especially with minimally invasive techniques, the rate of urinary complications can increase. Factors predisposing to urine leaks are well known. The most implicated factors are tumor size, endophytic nature, warm ischemia time, operative time, and hilar location of tumor.

Most minimally invasive techniques employ a transperitoneal approach. Symptoms can include ileus, fever, and abdominal pain. It is not clear whether leaving a drain would prevent these symptoms and lead to an earlier diagnosis. Regardless, many surgeons omit leaving a drain after minimally invasive partial nephrectomy given the very low incidence of urinomas. Urine leaks after open partial nephrectomy are contained in the retroperitoneum, however, resultant ileus, although rare, can also occur. On average, the mean postoperative day for presentation is 13 days (3 to 32 days) (Potretzke et al., 2016). Nearly 60% of patients will need to be readmitted for appropriate management. **Computed tomography with a urogram phase with contrast and delayed images to visualize the renal pelvis and ureter remains the mainstay for diagnosis as it can estimate the extent of urinoma or location of the leak accurately (Fig. 17.2).** The measurement of creatinine in the drain greater than 48 hours after surgery can help diagnose a urinary fistula but does not identify its location or severity.

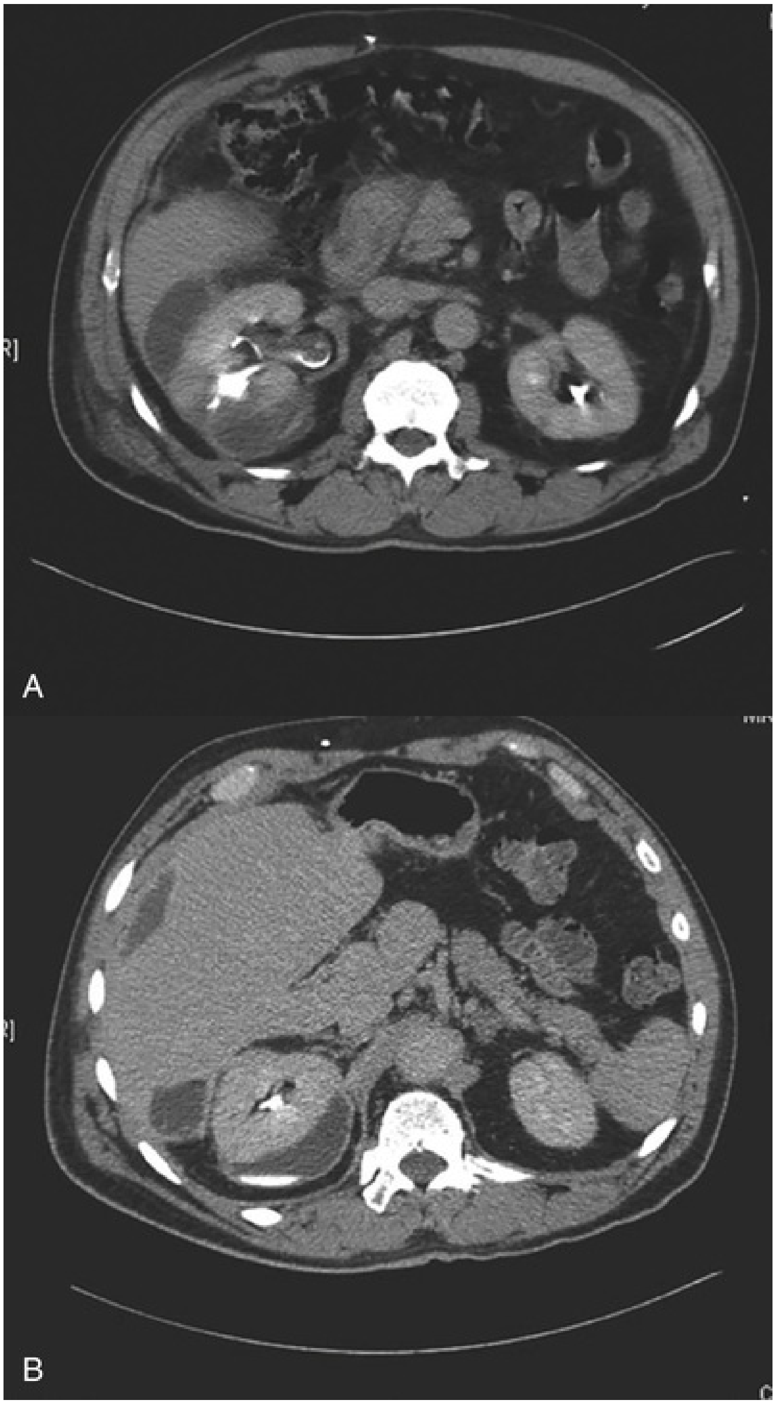

FIG. 17.2 (A) Delayed-phase computed tomography image revealing urinary leak after right laparoscopic partial nephrectomy. (B) Layering of contrast in retroperitoneum. (From Hakimi AA, Ghavamian R. Urinary and urologic complications of laparoscopic and robotic urologic surgeries. In: Ghavamian R, ed. *Complications of laparoscopic and robotic urologic surgery.* 1st ed. New York, NY: Springer; 2010:59–71.)

The recent adoption of robotic techniques has helped not only in the resection of the renal mass but also in the more facile reconstruction of the collecting system. Urine leaks can be avoided by proper identification and repair of collecting system entries during robotic partial nephrectomy. The visualization allows for optimal identification of calyceal entry. When suspected, retrograde infusion of methylene blue diluted in saline through a previously placed ureteral catheter helps identify the collecting system entry for repair. Collecting system entries are best repaired with absorbable sutures in a watertight fashion before parenchymal reconstruction.

Management

The management of renal leaks after open partial nephrectomy is the same as in robotic or laparoscopic partial nephrectomy. The pillar of management is a conservative approach as much as possible because the majority of these leaks will heal spontaneously as long as there is adequate drainage and no superimposed infection. To ensure adequate urine drainage, some patients require the surgical drain to be kept for a prolonged period.

The diagnosis is confirmed by sending the drain fluid for creatinine measurement. If the creatinine level is high, a urine leak is suspected. It should be noted that especially in robotic or laparoscopic procedures, initial increased drainage from the drain does not always indicate a urine leak. Because these are intraperitoneal operations, much of the increased drain output in the initial period could represent intraoperative blood and irrigation fluid that was in the peritoneal cavity and away from the surgical field while the patient was in the flank position but now drains as the patient lies in the supine position or becomes more mobile. Renal pelvic anatomy, although an uncommon variant, and patient age at time of surgery is shown to correlate with prolonged urine leaks defined as greater than 30 days (Meeks et al., 2008; Tomaszewski et al., 2014). **When a urine leak is suspected and demonstrated, the Foley catheter needs to be left in or reinserted. Increasing bladder pressures can theoretically increase upper tract pressures, exacerbating the leak. If the leak persists, ureteral stent insertion with a retrograde pyelogram will help reassess the severity of the leak and permit optimal drainage.** In one recent study, the need for secondary intervention was estimated between 4% and 38% depending on baseline patient and tumor characteristics (Tomaszewski et al., 2014). **If the urine leak persists despite the stent, the drain can be taken off suction because the latter can act as a siphon, keeping the fistula open, especially when positioned close to the location of the leak (Fig. 17.3). When**

this is suspected, the drain can be pulled out incrementally. Often urine leaks around the drain puncture site at the skin level and soaks the patient's dressings and skin around the drain site. To decrease the chance of skin excoriation and breakdown, a urostomy appliance can be positioned around the drain. The patient is instructed to keep a log of the outputs so that the clinician has an objective means to assess the resolution of the leakage.

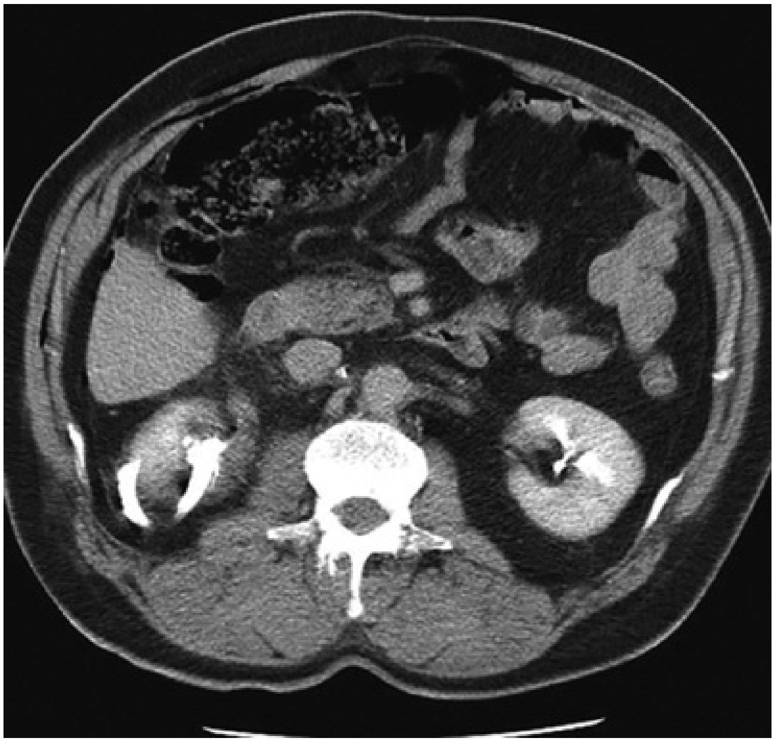

FIG. 17.3 Distal end of drain abutting the leak point, keeping the leak open and acting as a siphon. (From Hakimi AA, Ghavamian R. Urinary and urologic complications of laparoscopic and robotic urologic surgeries. In: Ghavamian R, ed. *Complications of laparoscopic and robotic urologic surgery.* 1st ed. New York, NY: Springer; 2010:59–71.)

Other described management strategies involve insertion of a second ureteral stent or percutaneous nephrostomy. Recently, ureteroscopy was reported to control urine leaks by a combination of caliceal fulguration and fibrin sealant application. Many small series report considerable success rates of novel techniques, but the mainstay of treatment remains proper drainage and management of the drains and catheters (Chu et al., 2015; Girard et al., 2014; Pardalidis et al., 2017). At any time during the management of these patients, surgeons should look for undrained collections or increasing amount of leaks, as these should prompt for better drainage usually achieved by interventional radiologic techniques (Fig. 17.4). Usually urine leaks will heal over time, and this can be seen as late as 80 days or more after surgery. Isolated reports of desmopressin are described but rarely employed. Unresolved refractory leaks leading to subsequent infection and prolonged morbidity for the patient can be managed by nephrectomy as a very last resort.

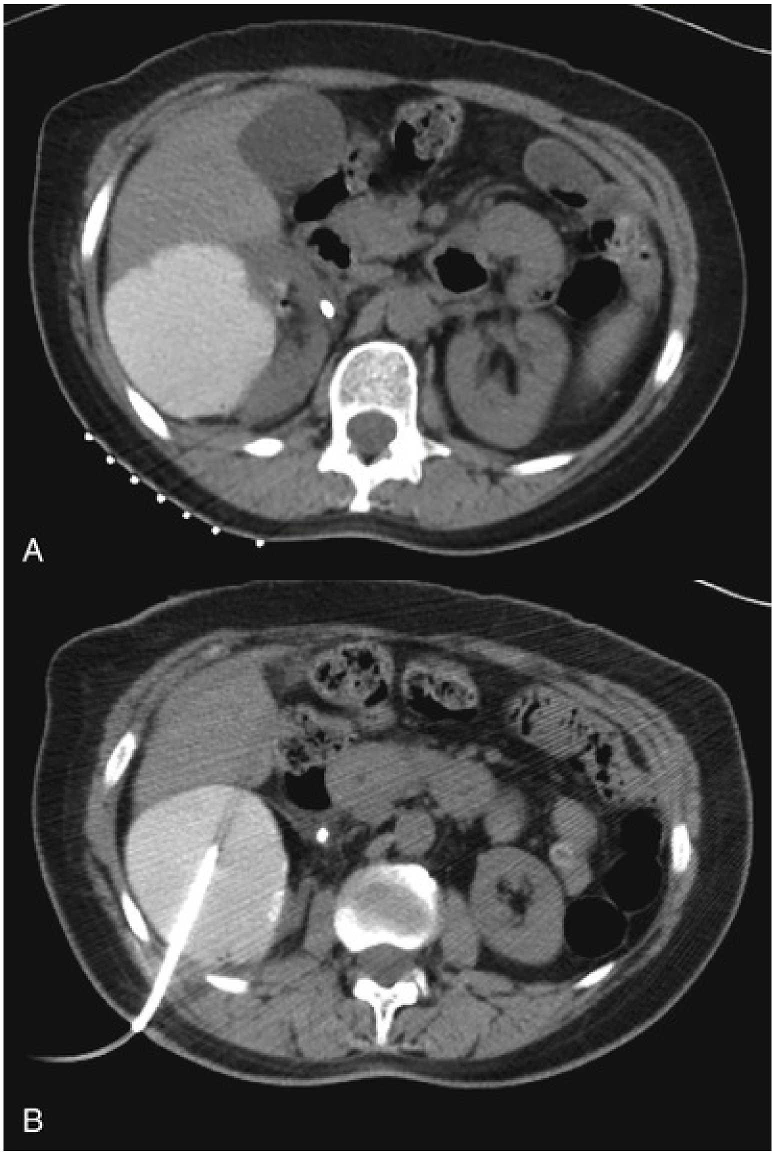

FIG. 17.4 (A) Delayed presentation of a large urinoma in right retroperitoneum after partial nephrectomy. (B) Percutaneous placement of a drain by interventional radiology.

Ureteral Injuries

Incidence and Anatomic Landmarks

Ureteral injuries could be the single most common surgical complication the urologist is challenged to manage, especially intraoperatively as consulted by other specialties. Despite the popular use of sophisticated sealing devices with most gynecologic surgeries, Blackwell et al. reported a 0.78% rate of ureteral injury during hysterectomy, with nearly 62% of those being unrecognized during surgery. Delayed recognition can lead to development of urinoma, ileus, sepsis, and shock with the need for nephrostomy tube diversion (Blackwell et al., 2018). Early recognition can have a great impact on morbidity, and the need for nephrostomy in early versus delayed recognition of ureteral injury was 2.3% and 23.4%, respectively.

Similar numbers can be identified in colorectal surgery, with rates of close to 1% during laparoscopic procedures. Risk factors include prior pelvic radiation, malignancy, prior abdominal surgery, adhesions, and extensive retroperitoneal lymph node dissection (Marcelissen et al., 2016). Some advocate the use of ureteral catheters before major pelvic operations, but there is no robust evidence for prophylactic placement of ureteral catheters to prevent injury. Some propose that routine ureteral stenting leads to ureteral edema and is associated with postoperative obstruction and acute kidney injury (Coakley et al., 2018).

During gynecologic procedures, the course of the ureter along the ovarian vessels and its close relation to the uterine artery and uterosacral ligament make it very vulnerable during ligation of these structures around the pelvic inlet and the infundibulopelvic ligament (Stany and Farley, 2008). A recent review of all laparoscopic hysterectomies found a 0.3% incidence of ureteral injuries, with all being in close proximity to the uterine artery and uterosacral ligament (Kiran et al., 2016).

Mechanisms of Ureteral Injury

Mechanisms of ureteral injury are very diverse ranging from pinpoint thermal injury that can be asymptomatic in the vast majority, to complete ligation and transluminal or partial transection. Partial or complete transections are the most commonly identified problems and are managed intraoperatively. Ligation and thermal injury have a more delayed presentation. Devascularization of the ureter can lead to delayed stricture formation or necrosis. The situation is distinctively different during urologic procedures. Permpongkosol et al. only identified six ureteral injuries (one intraoperative and five postoperative) in a study population of 2775 procedures. The best way to avoid ureteral injuries is to identify the ureter as early as possible, certainly before ligation of critical pedicles (Permpongkosol et al., 2007).

In summary, it is crucial to keep in mind important landmarks for the ureter during an ongoing surgery. The ureter can be injured proximally as it is in close proximity to the gonadal vessels. Later along its course, other common areas of injury are as it courses over the iliac vessels at the level of the pelvic brim. In the deep pelvis, the ureter can be damaged as it courses below the uterine vessels in the female patient. With the advent of robotic prostatectomy another potential area of injury is during the initial dissection of the seminal vesicles using a posterior approach initially during robotic prostatectomy. These anatomic sites can be of particular help during dissections, especially in tough situations such as retroperitoneal fibrosis or complex partial nephrectomy (Nies, 1998).

Intraoperative Management

A high index of suspicion is necessary to detect ureteral injuries. Depending on the operation performed, the surgeon must be cognizant of the locations at which ureteral injuries can happen. Certain anatomic landmarks can be used to help identify the ureter. In the upper abdomen, the ureter is in close proximity to the gonadal vessels and the lower pole of the kidney. In the lower abdomen, the pelvic brim is an excellent landmark. The ureter crosses over the common iliac artery, and one can dissect and isolate it and trace it from this location. If a ureter is injured with a needle that pierced transmurally, the suture must be removed and a ureteral stent placed endoscopically at the end of the procedure. The same principles can be applied for limited inadvertent thermal injuries to the ureter with monopolar devices and bipolar sealing devices.

Transection of the ureter requires more expertise, especially when one is willing to repair it laparoscopically. Partial tears with very reduced tissue loss and deterioration and no need for debridement can be closed primarily with 4.0 or 5.0 absorbable sutures after placing a stent through the ureterostomy. The stent will be left 4 to 8 weeks to allow enough time for healing (Figs. 17.5 and 17.6). When complete transection of the ureter occurs, the location of the injury mandates the repair strategy. For proximal transections in the upper two-thirds of the ureter, ultimately above the pelvic inlet, an open, laparoscopic, or robotic ureteroureterostomy can be performed after trimming both edges and performing adequate spatulated anastomosis. A stent should be left for optimal drainage.

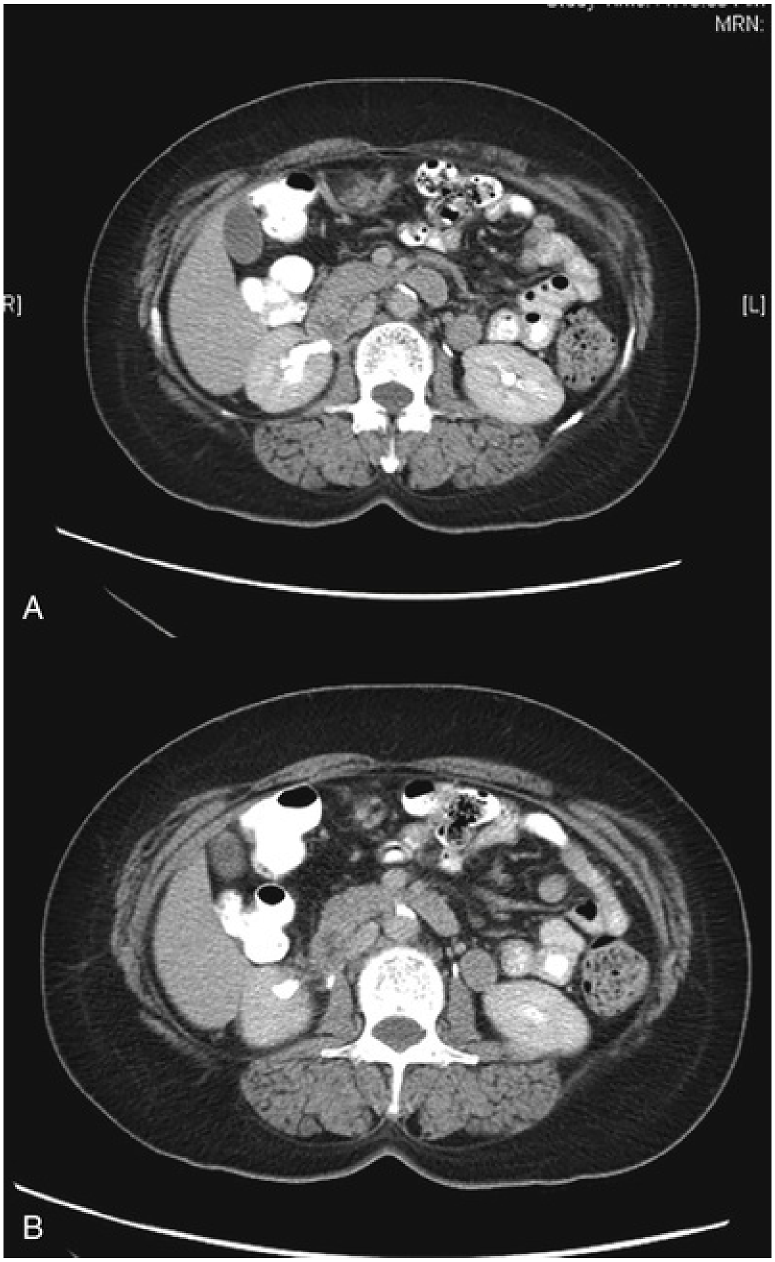

FIG. 17.6 (A) Delayed images of the patient in Fig. 17.5 taken 6 months after repair. (B) Contrast is seen in the lower pole collecting system and the ureter revealing excellent function and drainage.

A proficient minimally invasive surgeon could perform an ureteroneocystostomy with a psoas hitch without the need for open conversion. In the latter, a modified Gibson incision is usually enough in finalizing the new anastomosis. In rare circumstances, when tissue loss is extensive, a Boari flap is needed to compensate for extensive ureteral loss.

In all approaches, for all lesions recognized intraoperatively, the same principles apply. This is a tension-free anastomosis with a stent well-placed across the anastomosis and kept for at least 4 to 8 weeks in addition to a drain left in place to allow for adequate drainage of potential leaks or collections (Hoffman and Finan, 2013).

Presentation of Unrecognized Ureteral Injuries

Delayed recognition of ureteral injuries can be associated with significant morbidity as urine leaks lead to infection and urinary ascites, and sepsis could ensue. When the patient has a surgical drain, increased output through it should raise doubt for a ureteral injury. In gynecologic surgery, fistulous tract formation can occur between the ureter and vagina, representing 30% of indications for surgical repair in this scenario. In this same category of patients, ureteroneocystostomy was performed in the majority of the patients (70%) as the procedure of choice to manage the ureteral injury (Papanikolaou et al., 2013).

The preferred imaging modality to show the leak and delineate the extent of injury is computed tomography of the abdomen and pelvis with intravenous contrast and delayed images to visualize the full length of the ureter. Once the defect has been localized, it remains unclear when the exact and best time is for open or robotic ureteral repair and reconstruction when it is mandatory. Although many series have successfully compared early to delayed repair, it is agreed that every attempt should be made to manage the injury endoscopically with a primary ureteral stent or, alternatively, percutaneously with a nephrostomy tube and a stent placed in an antegrade fashion to bridge the gap in partial transections and small leaks (Li et al., 2012). Once all measures and attempts at endoscopic treatment and drainage have failed, it is agreed that waiting 6 weeks for surgical repair is safer as the inflammation has subsided by that time. In the early postoperative period, as long as the injury has been discovered in the first 7 days postoperatively and endoscopic management is considered inadequate, an early surgical repair could be attempted, as the inflammation is not extensive. Beyond this time, stent placement, percutaneous nephrostomy, or nephro-ureteral stent placement are all measures that aid in definite endoscopic management or temporarily until surgical repair is planned after 6 weeks. Stents should be left 4 to 8 weeks on average to allow time for the healing process, coinciding with the period in which inflammation decreases. All urinomas or collections must be drained, even when the leak has ceased, and interventional radiology can be of great help placing drains. In special situations in which severe infection is not controlled with antibiotics and collections ineffectively drain and persist, immediate surgical repair is the only means to manage these challenging cases regardless of the timing from surgery. Typically, these surgeries require expertise to address such injuries and surrounding tissue inflammation to achieve an optimal repair.

Ureterovaginal Fistula

The diagnosis of ureterovaginal fistula can be challenging, as this is often a delayed presentation. Usually the patient complains of ongoing incontinence. When the diagnosis is suspected, giving the patient intravenous methylene blue and clamping the Foley should stain a vaginal pad blue in the presence of a fistula. Sometimes a ureterovaginal fistula coexists with a vesicovaginal fistula. **In these circumstances, the presence of a vesicovaginal fistula must be ruled out and differentiated from a ureterovaginal fistula.** The double-dye pad test consists of giving the patient a load of oral pyridium while filling the bladder with methylene blue followed by clamping of the Foley catheter. A pad is placed in the vagina. An orange stain indicates a ureteral fistula, whereas blue staining is in favor of a vesicovaginal fistula. The presence of a blue stain distally and an orange stain proximally in the pad signifies concomitant presence of both fistulas.

Strictures

Despite adequate repair, stricture formation at the site of injury or fistula can occur. With the current advantages of laser and balloon dilators, endoscopic attempts to manage such complications are reasonable as an initial technique, especially for short and nonextensive strictures. **Definitive surgical repair may be necessary when the initial endoscopic attempt fails or the ureteral stricture is extensive and long (>2 cm).** It is often a challenging procedure because of ensuing fibrotic changes in the retroperitoneum that result from the previous urinary leak or ureteral injury. The principles of repair remain the same as discussed previously. **For upper ureteral injuries, where the ends can be mobilized and approximated, a ureteroureterostomy can be attempted for small segmental defects.** Recently, advanced reconstructive techniques with the use a robotic platform have been described to bridge extensive gaps with buccal mucosa grafts. The appendix is also described as a reasonable conduit to bridge ureteral defects on the right side. The advent of robotics has aided in the management of such injuries (Musch et al., 2013). One can assess the adequacy of vascular perfusion in the transected and "trimmed" ureteral ends with the Fire Fly technology of the robot. Intravenous infusion of indocyanine green fluorescence (ICG) can provide an objective assessment of ureteral health and vascularity before definitive repair (Bates et al., 2016). A ureteral repair is then attempted robotically. **Classic techniques of ureteral reimplantation with a psoas hitch for lower ureteral defects and a Boari flap for mid-ureteral injuries can be attempted robotically.** Upper ureteral strictures that are extensive are at times best managed with an ileal ureter interposition graft. Of course, open techniques for reconstruction should always be considered when significant intraabdominal challenges exist, such as multiple prior surgeries and adhesions that would render a robotic or laparoscopic repair not only difficult and lengthy but also at times impossible.

Prevention of ureteral injuries is key. Many strategies have been adopted to avoid such complications. This ranges from preoperative stenting of the ureters to lighted stents to aid more in localization when haptic feedback is limited, especially in the case of minimally invasive surgery.

Lower Tract Urinary Complications

Bladder Injuries

Bladder injuries are rare during robotic and laparoscopic urologic injuries. However, bladder injuries are more common during gynecologic and at times colorectal procedures. The bladder is at risk for injury during a hysterectomy during the creation of a bladder flap when the bladder dome is dissected from the lower uterine segment. Intraoperative recognition is key, and repair can be performed in two layers with absorbable sutures. A urethral catheter should be left for 7 to 10 days to ensure adequate healing and decrease the risk for subsequent vesicovaginal fistulas. Postoperative presentation can mimic ureteral injuries with abdominal distension, ileus, fever, chills, leukocytosis, and increased drainage from pelvic drains.

Diagnosis is established with a computed tomography cystogram. Intraperitoneal leaks are managed with robotic or open repair in two layers with absorbable sutures. On occasion, when a small, contained extraperitoneal leak is evident, management can be conservative with urethral catheter drainage. Often after hysterectomy, definitive repair of extensive bladder injury is the best option as the patient would be at risk for vesicovaginal fistula formation.

The most common complication at the bladder level at the time of urologic surgery is during robotic radical prostatectomy, when at times a “buttonhole” defect is created at the posterior bladder lip during dissection of the posterior aspect of the vesicoprostatic junction. Care must be taken to identify the correct plane for dissection without denuding the posterior bladder neck extensively. It is crucial to always identify the ureteral orifices when difficulty exists in dissection at this location resulting from previous endoscopic surgery of the prostate (e.g., transurethral resection), microwave therapy, or large prostates with the presence of an extensive median lobe. Temporary placement of 5-Fr pediatric feeding tubes or preoperative stenting may be necessary. Both maneuvers are helpful for the less experienced surgeon and rarely are necessary for the experienced robotic surgeon.

Another scenario is leakage from the site of a bladder cuff resection at the time of an open, robotic, or laparoscopic distal ureterectomy and reimplant or after an open, robotic, or laparoscopic nephroureterectomy. Management remains as outlined earlier, and resolution of the leak will occur as long as the leak and bladder are adequately drained for 7 to 10 days.

Urine Leaks After Radical Prostatectomy

Overview

Urinary leakage at the urethrovesical anastomotic junction is one of the most common complications in the early postoperative period (days 7 to 10) reaching an incidence of 0.3% to 15.4%(8). **Although no exact definition of urine leakage after radical prostatectomy exists, it consists of an increase in drainage from the surgical drain along with a proportional decrease of drainage from the urethral catheter.** It is confirmed by contrast extravasation from the anastomosis on cystography. The contrast extravasation is usually posterior along the possible weakest point of the anastomosis, although other areas of the anastomosis can leak also.

Early catheter removal on postoperative day 2 has been assessed in a comparative study for techniques of urethrovesical anastomosis including posterior reconstruction. Although this did not show an increased risk for urine leaks, early catheter removal remains an uncommon practice, with most surgeons recommending a 7- to 10-day catheterization requirement (Gratzke et al., 2016).

Classification of urine leak severity will have to follow the Clavien-Dindo grading system in an effort to standardize reporting. It is evident though that attempts for grading urine leaks depended mainly on the need for intervention for proper management. **Clinically significant urinary leaks consist of collections extraperitoneally in open radical prostatectomy or intraperitoneally after robotic prostatectomy.** These can result in ileus, requiring extended hospital stay and intravenous fluids. When associated with fever and signs of sepsis, antibiotic therapy or percutaneous drainage is warranted (Mochtar et al., 2007; Tan et al., 2010). The incidence of re-intervention for vesicourethral anastomotic leakage ranges from 0.5% for open procedures to 2.5% for some early series of robotic-assisted or laparoscopic radical prostatectomies. With increasing experience with robotic prostatectomy and the utilization of a watertight running anastomotic technique, the incidence of urinary extravasation has decreased. Then long-term sequelae can be a bladder neck contracture and a resultant fibrotic bladder neck. This can potentially contribute to a decrease in continence if the scar involves the external sphincter mechanism by decreasing sphincteric coaptation and function.

Contributing Factors

Postoperative blood loss is a predictor for the development of urinary extravasation. A postoperative hematocrit drop of more than 6 points identifies a group of patients at increased risk for urine extravasation. Other contributing factors are obesity, length of the operation, size of the bladder neck, and utilization or lack thereof of bladder neck reconstructive techniques (Fenig et al., 2006; Gnanapragasam et al., 2005). Some surgeons utilize a double-armed barbed suture rather than monofilament sutures to allow for sequential tightening of the running anastomosis in an effort to better attain a watertight anastomosis. However, the use of monofilament or barbed suture does not seem to affect rates of urine leakage after prostatectomy (Sammon et al., 2011).

Challenging radical prostatectomies such as salvage prostatectomies are associated with considerable complication rates. This is caused by a suboptimal urethrovesical anastomosis resulting from compromised quality of surrounding tissue from previous therapies or radiation (Ogaya-Pinies et al., 2018). Recently, attempts to decrease the associated morbidity of such operations were successful in decreasing urine leaks from 35% to 6% using tissue biografts scaffolding. However, every attempt at reconstruction using a watertight anastomosis can help in reducing the incidence of leaks.

In a large cohort, Tewari et al. showed that the incidence of urine leaks was also less after robotic radical prostatectomy when the vesicourethral anastomosis was achieved along with anterior reconstruction (1%) or total reconstruction (0.3%) compared with conventional apposition (2.3%) (Tan et al., 2010; Tewari et al., 2012).

Diagnosis

In case of a large leak, the diagnosis is rather straightforward. There is an increase in drainage from the surgical drain with an often (but not necessary) proportional decrease in urethral catheter output. **When suspected, the drain fluid can be sent for creatinine content, which will be high when a definite leak exists.** To help establish the diagnosis, retrograde cystography can be considered a valuable and contributive tool (Han et al., 2011). **Other imaging modalities such as computed tomography cystography can be utilized and are useful adjuncts in cases of concomitant fever and leukocytosis to rule out a concomitant collection (Figs. 17.7 and 17.8).** It is crucial to ensure that the urethral catheter is in place and draining optimally. Traction should never be employed as it can further disrupt the anastomosis and risk contracture formation.

2010:59–71.)

Management

The healing of a vesicourethral urine leakage is time-dependent. Leakage when detected in patients on postoperative day 8 was subsequently found in 20% of patients on postoperative day 14 and in 8% of patients in 3 weeks (Hakimi et al., 2012). All measures to manage leakage allow more time for the healing process in the absence of intraperitoneal leak, ileus, or sepsis.

Most urinary leaks are small, can be managed conservatively, and will spontaneously resolve with prolonged urethral catheter drainage. The initial step after fluid creatinine measurement is to ensure patency of the urethral catheter as the most important part of management is ensuring adequate bladder drainage. Side-fenestrated catheters have been known for better urine drainage and should be replaced if other types of catheters have been used (Moinzadeh et al., 2004). This can be achieved safely under radiologic guidance in some instances. If on computed tomography the drain is too close or overlying the anastomosis, it can be advanced and readjusted. In these instances, the drain can act as a siphon, encouraging the patency and persistence of the leak. The drain can also be taken off of bulb suction to allow for a more passive drainage mechanism. Large collections, especially when the drain has already been removed, should be managed by percutaneous drainage by interventional radiology to prevent abscess formation (Figs. 17.9 and 17.10).

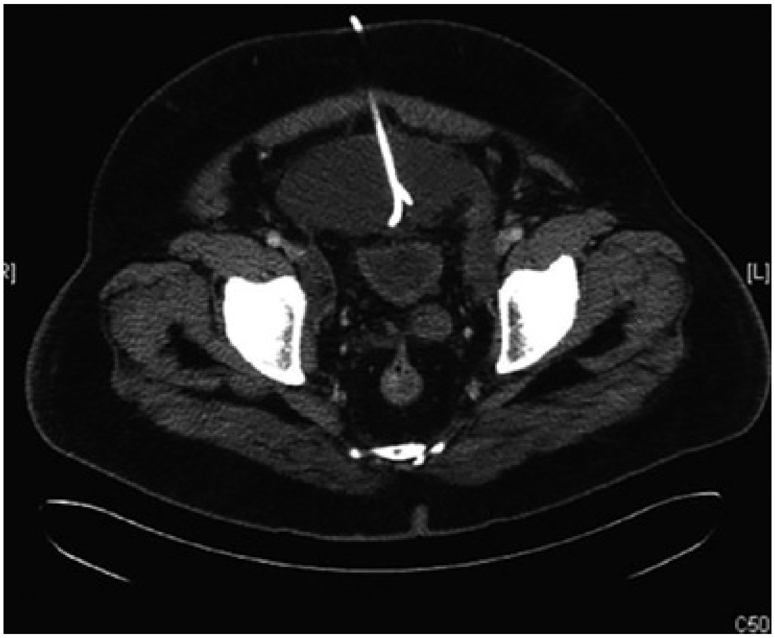

FIG. 17.9 Percutaneous drain placement in the anterior collection. (From Hakimi AA, Ghavamian R. Urinary and urologic complications of laparoscopic and robotic urologic surgeries. In: Ghavamian R, ed. *Complications of laparoscopic and robotic urologic surgery.* 1st ed. New York, NY: Springer; 2010:59–71.)

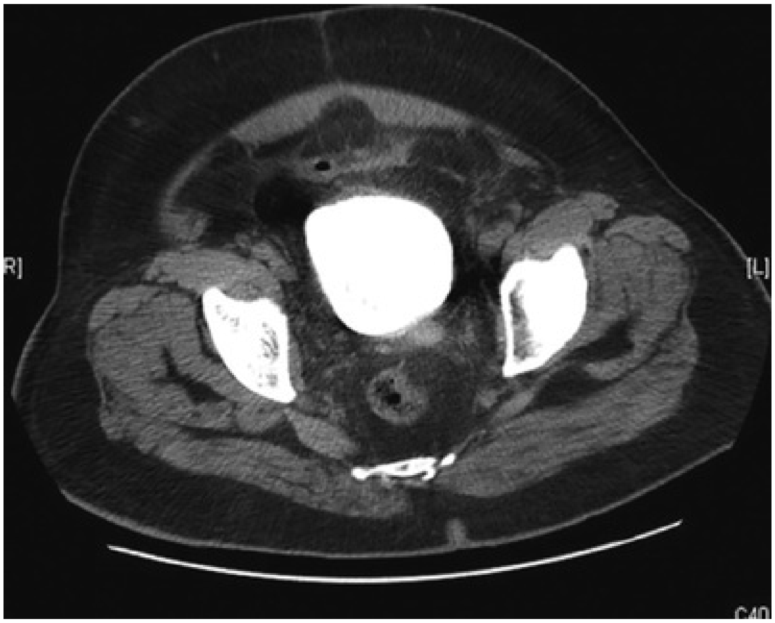

FIG. 17.10 Follow-up computed tomography cystogram of the patient in Fig. 17.7 revealing resolution of leakage.

If these measures fail to control the urine leak, then other conservative maneuvers can be attempted. These involve connecting the Foley catheter to suction to ensure maximal urine drainage across the anastomotic defect. Using a vented 18-gauge angiocatheter needle and connecting the Foley catheter to low intermittent wall suction tubing, or coupling an underwater pleural suction system (Pleur-evac) to the urinary catheter are the most reported and studied techniques (Shah et al., 2009). Continuous wall suction is counterproductive because of obstruction of the catheter holes with bladder mucosa.

Nephroureteral stents connected to a special suction drainage mechanism have been employed to minimize and ultimately stop a persistent leak (Fenig et al., 2006). Initial laparoscopic series reported that 1.6% to 2.2% of patients treated with laparoscopic radical prostatectomy required nephrostomy placement to control the leak (Mochtar et al., 2007). This effectively diverts urine output away from the new vesicourethral anastomosis, but it does not ensure its patency. These measures are extreme and rarely utilized or needed. A useful maneuver for total urinary diversion would be attempted cystoscopy with placement of open-ended ureteral catheters. This can be attempted gently under anesthesia. The ureteral orifices are identified, and open-ended catheters are passed under fluoroscopic guidance. The distal ends of the catheters are then exteriorized to the urethral catheter, essentially rendering the anastomosis dry. This maneuver should only be attempted when partial disruption exists and the orifices can be identified easily as cystoscopy in this setting risks total anastomotic disruption.

When all attempts at repair fail and substantial or total anastomotic disruption is suspected, repair is usually undertaken with a formal reconstruction. In the case of robotic radical prostatectomy, this can be attempted robotically. When major disruption is suspected in the early postoperative period, a formal early repair decreases the chance for ileus, infection, prolonged hospital stay, and long-term potential sequelae such as incontinence and bladder neck contracture. Delayed repair after postoperative day 7 is rarely embarked on as the tissues are friable and do not lend themselves for easy reconstruction. Here a computed tomography cystogram is mandatory, and placement of a percutaneous drain is essential, especially when the original operative drain has already been removed. Administration of parenteral antibiotics is essential when fever or leukocytosis is present. In this scenario, conservative measures with maximal drainage of the bladder and urinoma are essential, and resolution and recovery, albeit prolonged, will result.

Vascular Complications

Overview

Vascular injuries are the most dreaded complications during urologic surgery. Their significance is even more pronounced in the era of minimally invasive surgery. **They are among the most common major complications of laparoscopic and robotic surgeries and constitute the most common type of intraoperative complications.** One would expect the rates of major vascular injuries to decrease over the years as surgeons gain more experience. A thorough audit report indicates similar findings, except for the decrease of serious and major complications from 10% to 4% over the years (Davenport et al., 2006). However, more recent reports do not support this notion. This might be in part caused by the introduction of new surgeons and their advancement through their learning curve and the adoption of minimally invasive options for more complex urologic procedures. These injuries can occur at any time during the procedure. For minimally invasive procedures, they can occur while gaining access, during tissue dissection, or when isolating and dissecting major or minor vessels.

Vascular injuries can present intraoperatively or postoperatively. They can be largely avoided by careful attention to surgical technique and anatomy. Although exceptions exist, most major vascular injuries occur intraoperatively, and most postoperative bleeding is the result of unrecognized bleeding from smaller vessels. The consequences can be devastating when massive bleeding and hemodynamic instability occur and can result in major blood loss, major hemodynamic instability, shock, multiple organ failure, and death.

The key to management is early and prompt recognition and a calm response, especially when encountered intraoperatively. The challenge in managing these complications during minimally invasive surgery compared with open surgery is lack of manual compression for control of major vessels, selective use of instruments through available ports such as suction or vascular clamps, and difficulty in introduction of lap pads and sponges in the field to tamponade the bleeding and improve exposure. **In the event of major vessel injury, immediate conversion to an open operation, and prompt manual compression and control is key to a more favorable outcome.** It is prudent to obtain an intraoperative emergent vascular consult.

In this section, we discuss the incidence, diagnosis, and management of intraoperative and postoperative vascular complications including some common vascular complications of upper tract and lower tract urologic procedures.

Intraoperative Vascular Complications

The rate of vascular injuries during minimally invasive surgery is reported to be between 2% and 3% in urologic series (Breda et al., 2009). As a means for comparison, in nonurologic procedures, vascular injury rates are around 0.5% for minor procedures and can be as high as 20% for major procedures like hepatic resections (Kenney and Tuerk, 2008; Laurence et al., 2007; Siqueira et al., 2002). The proximity of the dissection to major blood vessels in upper tract procedures and the exceptional abundance of large- and medium- size vessels encountered during partial nephrectomies make these procedures prone to inadvertent vascular injuries. Surgical procedures of the lower urinary tract share many similarities with regard to complications when involving extended lymph node dissection along the iliac vessels, but complications remain relatively uncommon. Most urologic vascular injuries are related to dissection of major vessels. This is especially true for the kidney, a parenchymous organ with a rich blood supply. In nephrectomy and partial nephrectomy, dissection of major renal vessels off of the aorta and vena cava is needed.

Colombo et al. (2007) reviewed 1867 laparoscopic cases. The most common intraoperative complication was hemorrhage occurring in 2.3% of the cases. The incidence of postoperative hemorrhage was 2.7%. Hemorrhage accounted for 40% of all perioperative complications. In a review of 2775 laparoscopic urologic procedures, Permpongkosol et al. (2007) found that the two most common complications were intraoperative vascular injury (1.98%) and bleeding requiring transfusion (1.76%). Bleeding was more common in procedures around major vessels such as retroperitoneal lymph node dissection. Postoperative bleeding and drop in hematocrit occurs postoperatively evidenced by a hematocrit drop in 2.7% of patients. Similar numbers were reported by earlier and more recent series analyzing the outcomes of laparoscopic urologic procedures (Breda et al., 2009; Colombo et al., 2007; Permpongkosol et al., 2007; Simon et al., 2004).

Vascular surgery is the most common reason for conversion to open surgery. The rate for open conversion depends on the type of laparoscopic surgery being performed and on different series. Parsons et al. (2004) reported a 2.6% vascular injury rate in a series of 894 cases. In this series, vascular injuries accounted for 12 of the 13 open conversions. Laparoscopic live-donor nephrectomy keeps a higher incidence of emergent open conversion (Siqueira et al., 2002). In large academic centers, rates of open conversions were once reported to be near 1.5% and death near 0.2%, with the latter remaining very rare (Parsons et al., 2004). **Patient factors responsible for vascular complications and conversion to open surgery are previous abdominal surgery, concomitant abdominal pathology, obesity, and aberrant vascular anatomy.** The rates of vascular complications have also been shown to be expectedly and directly related to surgeon experience. It is for this reason that judicious case selection in one's initial surgical career and experience is key to avoiding major injury.

Management

The cognitive reaction of the surgeon to bleeding is considered the very first step in managing a vascular injury during laparoscopic or robotic urologic surgery. Control of the bleeding can be difficult and time-consuming, with compromised vision through the laparoscope. A study looking at improving these delays reported that reaction time is usually within 22 seconds, the time to control is within less than 1 minute, and the amount of time spent to repair is within 3 minutes. This accounts for 170 seconds on average, although lengthier repair periods are seen when the bleeding structure is temporarily controlled.

Algorithms have been designed to minimize blood loss and decrease the delay in management and further complications when an acute bleed occurs. A consensus summary proposed by Passerotti et al. is as follows (Passerotti et al., 2016). Increasing the pneumoperitoneum and intra-abdominal pressure to decrease venous bleeding should be done with caution as this puts the patient at risk for air embolus, especially when major venous injury has occurred. Aspiration and better exposure of the problematic site is key. Adequate and working suction devices and introduction of laparoscopic sponges for local control and better evacuation of blood are necessary. The decision to add laparoscopic ports should be made expeditiously but wisely to accommodate infield suction devices or vascular clamps while staying away from the work area of other trocars. Once all injuries are identified, especially in complex cases in which associated injuries need to be ruled out, repair is undertaken. Application of surgical clips should be judicious and not random (Figs. 17.11 and 17.12). When clips fail, they can complicate attempts at suture repair and subsequent application of stapling devices and additional attempts at suture repair, which remains the most reliable rescue measure for any damaged vessel. When the exposure is adequate and the bleeding is identified, select major vascular repair can be performed by the experienced minimally invasive surgeon who is adept at intracorporeal suturing (Figs. 17.13 and 17.14). In robotic surgery, the bedside assistant is key to maintaining exposure and providing pressure using the tip of the suction device with selective suctioning as needed. Vascular clamps can be applied selectively, allowing for a controlled repair. There should be a low threshold for conversion to open surgery and obtaining a vascular surgery consult.

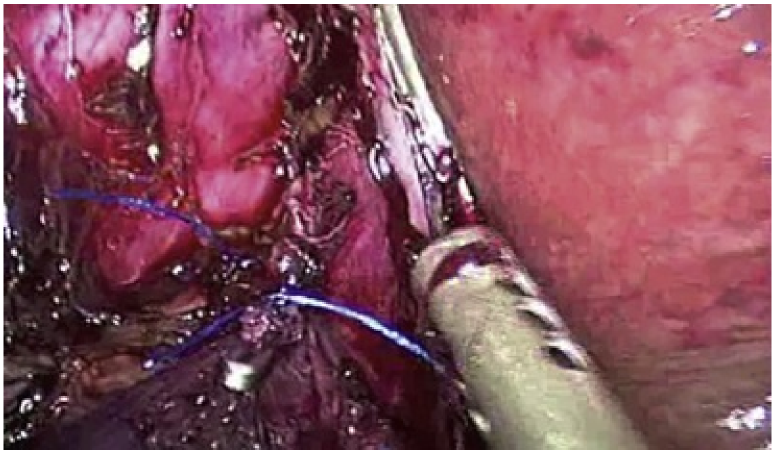

FIG. 17.14 Completed repair with interrupted sutures.

Vascular Injury During Abdominal Access

Access-related injuries to vascular structures have become very rare, with a reported incidence of 0.1%, but they can present a major challenge. A recent meta-analysis revealed a mean vascular injury rate of 0.044% while attempting blind insufflation and access to the abdominal cavity (Larobina and Nottle, 2005). Access-related injuries can result from Veress needle or trocar-related injuries. Aspiration of frank blood through the Veress needle when trying to obtain access is a red flag. Insufflation should be discontinued as this can cause CO_2 embolization with devastating consequences if a major vein is entered. **The signs of gas embolism can vary from a subtle change in hemodynamics: which include sudden hypoxia, hypercarbia, hypotension, arrhythmia, or cyanosis during insufflation. There could be a characteristic "mill wheel murmur."** The gas bubble can travel to the right heart or pulmonary artery. This results in obstruction of venous return and a reduction in cardiac output, leading to reduced pulmonary blood flow, pulmonary hypertension, and right heart failure. Asymptomatic air emboli are worrisome as they carry a high risk for death when systemic changes such as drop in mean arterial pressure or heart rate occur. Elevated right heart pressures and cyanosis of the head and upper extremities can occur. There is a reduction in end-tidal $CO_{2.}$ Transesophageal echocardiography can detect a gas bubble as small as 0.02 cc. **Treatment is immediate desufflation, administration of 100% FiO_2, and placement of the patient in the Trendelenburg and left lateral decubitus position to trap the air bubble in the right atrium. Then a central line is inserted in an attempt**

to aspirate the air bubble.

Whether needle- or trocar-associated injuries are suspected, once inside they should not be removed and should be kept in place without additional manipulation. When alternate access is established, this can help identify the site of injury and sometimes tamponade the bleeding in the case of trocar injury. Management depends on the extent of injury. A point puncture of a major vessel such as the aorta and vena cava with a Veress needle can be self-limiting as long as there is no expanding hematoma. Direct exposure and assessment is key. Trocar injuries are usually more extensive and almost always require repair and conversion to open surgery as devastating consequences can ensue. Through-and-through injuries in the front and back wall of the major vessels have been reported, and this can only be repaired reliably in an open fashion. Management of such injuries, once precisely delineated, is multidisciplinary, involving aggressive resuscitation by the anesthesia team, vascular surgery consultation, and open conversion if necessary. Many times depending on the experience of the surgeon, the injury can be repaired laparoscopically or robotically.

In most scenarios, full insufflation to 15 to 18 mmHg is needed to provide a taut abdomen for insertion of the trocars. Once all trocars are in, the pressure can be lowered to 12 to 15 mmHg for the remainder of the operation. A common insufflation device for robotic surgery is the AirSeal system. This system provides a valve-less trocar that can be used to maintain pneumoperitoneum while providing constant smoke evacuation. The constant insufflation and the trocar's special design prevent air leakage, providing a stable pneumoperitoneum. Although one advantage is maintaining pneumoperitoneum, it also provides lower tensile pressure on the abdominal wall and diaphragm, which can be beneficial in ventilating patients, especially in compromised surgical positions such as the steep Trendelenburg or flank position. The abdominal wall is therefore more lax, and it is crucial to insert all trocars with standard insufflation before switching on the AirSeal mode.

Mechanisms of Injury

Particular care is necessary at the level of the umbilicus given the proximity of the common iliac vessels and the aortic bifurcation. The relationship of the umbilicus to the iliac bifurcation varies widely from 5 cm cephalad to 3 cm caudally in both supine and Trendelenburg positions, and it is not always considered a reliable anatomic landmark for safer access.

The angle of entry of the Veress needle was implicated to play a role. In general, the Veress needle must be inserted at an angle between 45 degrees for patients with a normal BMI and 90 degrees for obese patients at the level of the umbilicus. This depends on the body habitus of the patient as the umbilical base moves caudally in relation to the aortic bifurcation as BMI increases. **In most situations, with the aortic and vena caval bifurcation near the umbilicus in general, the most likely vessel injured directly with an umbilical Veress needle or trocar is the left common iliac vein.** In thin patients, extra attention is needed as the distance between the abdominal wall and retroperitoneal structures can be as little as 2 cm. This distance is around 6 cm in the average patient, although it can markedly decrease in the Trendelenburg position, which brings the aortic bifurcation hazardously closer to the skin, especially in thinner patients. Some studies evaluated the utility of the anterior superior iliac spine (ASIS) as a more reliable anatomic landmark. The surgeon must be aware of abnormal or pathologic anatomic considerations. Many patients have concomitant vascular disease and an atherosclerotic aorta such as an abdominal aortic aneurysm (AAA) and aberrant or tortuous aorta, or common iliac arteries. In these patients, even a small puncture with the Veress needle could be more devastating and cause a “mini-fracture” of the aortic wall, as there will be a lack of elasticity and ability for spontaneous tamponade. This scenario is especially alarming in patients with an AAA in the vicinity or just above the iliac bifurcation. In these patients, the Veress needle has even a shorter distance to travel to the retroperitoneum to potentially cause a devastating injury. In this scenario the aneurysmal wall is diseased, and spontaneous tamponade may not occur. Furthermore, atherosclerotic plaques can embolize to lower extremities with devastating ischemic consequences. If the presence of an AAA is known or suspected before the operation, an alternative site for Veress needle entry such as the left upper quadrant can be used. It is also helpful to review preoperative cross-sectional imaging if available. If not, it is wise to obtain imaging for planning purposes.

Apart from the umbilicus, when the patient is in the lateral flank position for kidney procedures, the Veress needle can be safely used for entry. Classically, the left upper quadrant and the right upper quadrant provide a safe area for Veress needle insufflation. On the right side, deep entry by the Veress needle can puncture the liver as it drapes over the upper pole of the kidney. On the left side, splenic injuries are uncommon with the Veress needle unless a patient has splenomegaly. Despite the fact that these locations are classically reported as safe, the Veress needle can be applied safely in most locations in the abdomen. In robotic kidney surgery, the initial Veress needle can be placed where the camera trocar would eventually be placed; this is usually two fingerbreadths above the umbilicus in the lateral rectus line. The Veress needle must be pointed perpendicular to the posterior peritoneum to avoid injury to the bowel, which may be displaced more medially with the lateral position. Again, for cases in which there is a history of extensive abdominal surgery, open Hasson trocar or visual optical trocar as the initial entry mechanism can be employed as discussed later.

Comparison of Different Access Techniques

The inadequacy of reporting major and minor injuries during laparoscopy or robotic surgery underlies the difficulty in assessing the safety of respective techniques. For instance, a report by the US Food and Drug Administration (FDA) showed that 81% of deaths from trocar incidents were caused by major vessel injuries. The most commonly affected are the aorta, inferior vena cava, and iliac vessels, with the latter rarely resulting in a fatal outcome (Pereira et al., 2010).

Many techniques including the open Hasson technique and special bladeless trocars have been developed to prevent access injuries (Minervini et al., 2008). There is no consensus as to which technique is safer to use or preferred for less experienced surgeons. **The Hasson technique has classically been advocated to be the safest approach for inexperienced surgeons and in patients with previous abdominal surgery when extensive adhesions are suspected.** Regardless, Veress needles continue to be most commonly and widely used for access, although some old reports state a slightly higher risk for vascular complications (Molloy et al., 2002). This did not seem true in a recent Cochrane-based review indicating only higher access failure rates with Veress needles (Ahmad et al., 2015).

Currently, the optical bladeless trocar has been commonly used, and it provides extra security with visual feedback while going through the consecutive layers of the abdominal wall. Thomas et al. reported the rate of injuries as less than 0.31% in a large series of more than 1000 urologic procedures. Most of these were not major vascular injuries, with reported injuries to mesenteric or epigastric vessels (Thomas et al., 2003). When compared with the Hasson technique, optical bladeless trocars required markedly less time for placement and establishment of pneumoperitoneum (125 vs. 440 seconds) (Minnervini et al., 2008). Other safe devices that need to be mentioned are those that control axial force for penetrating the abdominal and fascial layers, as injuries mainly occur when excessive forward force is employed. The most common method involves introducing first an expandable sheath through which a cone-shaped port placement is achieved. While guiding trocar entry, it will help push away blood vessels and reduce the forceful hand movement by countertraction on the elastic outer sheath and simultaneous added control by the surgeon's nondominant hand. The rotational movement in trocar introduction in general is key. The trocar should also be introduced with two hands, the dominant hand controlling the top of the trocar and exerting the entry force while the nondominant hand is at the shaft of the trocar at the skin level to avoid sudden uncontrolled entry. It is crucial for the skin incision to be large enough to accommodate the shaft of the trocar. Otherwise, the trocar shaft will indent the skin, and the peritoneum and more excess force will be needed to push the trocar, resulting in sudden, uncontrolled entry and injury of deeper anatomic structures regardless of location.

Management of Vascular Incidents

Vessel injuries and their extent are assessed by suction, irrigation, and direct visualization with pressure and control above and below the area of bleeding in major open surgery. In case of major vessel injury, an extra suction device is advisable. A vascular surgery consult should be obtained if additional help is needed. Specific steps are necessary for prompt and efficacious control of laparoscopic intraoperative vascular injuries. A transient increase in abdominal pressure to 20 to 25 mmHg while maintaining the peritoneum is advised. In the case of major vessel injury, this step must be taken with caution as the risk for air embolism is increased. However, pneumoperitoneum can aid in delineation and temporization of even medium to large venous defects (Fig. 17.15). Direct pressure can be applied with gauze or a rolled Surgicel with the suction device by the bedside assistant. If the bleeding is under control, accessory trocars can be placed, and the operation can be continued laparoscopically if control and repair can be achieved. Open conversion is advisable if the extent of the injury cannot be delineated and control and repair cannot be achieved. There should be a low threshold for open conversion, and transfusion must be started as necessary before major volume depletion and hemodynamic instability occur.

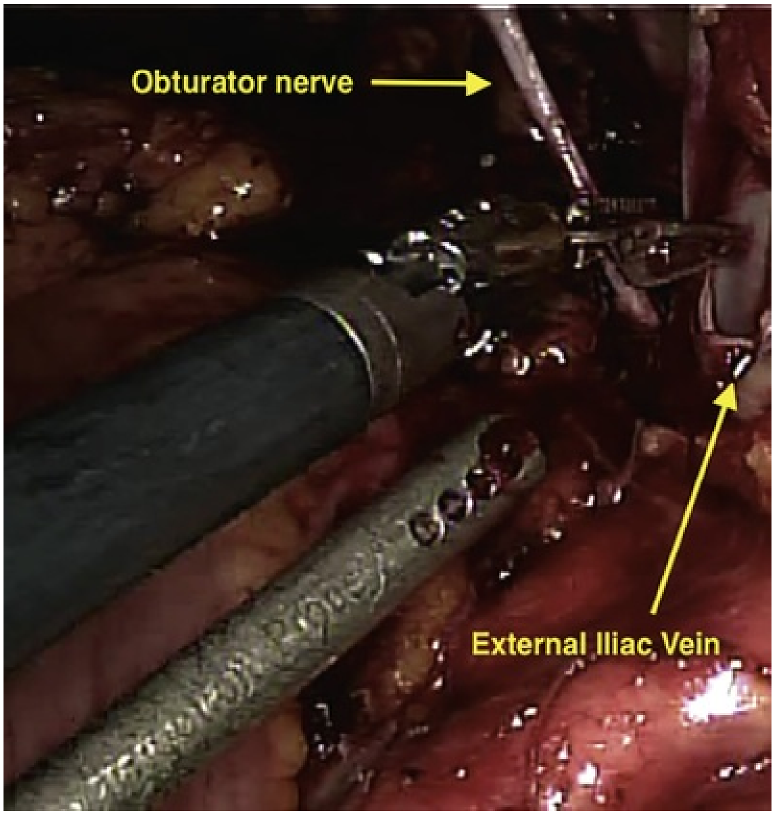

FIG. 17.15 During right robotic pelvic node dissection, the external iliac vein is partially transected. The endothelium of the vein can be easily appreciated. (From Tare D, Maria P, Ghavamian R. Vascular complications in laparoscopic and robotic urologic surgery. In: Ghavamian R, ed. *Complications of laparoscopic and robotic urologic surgery.* 1st ed. New York, NY: Springer; 2010:45–58.)

Injury to Epigastric Vessels

Epigastric vessel injuries occur in 0.2% to 2% of cases and constitute a special situation in which delayed presentation is common because trocars can tamponade the damaged vessels throughout the surgery (Joy et al., 2016). The epigastric vessels course in the lateral aspect of the rectus sheath. Most trocars are placed lateral to these vessels along the pararectal sheath. When trocars are displaced medially after entry to the skin, epigastric vessels can be injured. Although many studies have assessed the average distance of the epigastric vessels from landmarks like the ASIS or midline, an easy preventive measure is to ensure adequate transillumination of the abdominal wall before gaining access with additional ports. Lateral ports should be at least 5.5 to 6 cm lateral to the midline to avoid the epigastric vessels. Careful inspection of these sites once trocars are removed is essential (Pickett et al., 2010). Many techniques have been evaluated for repairing epigastric vessels. A Foley catheter placed across the port site with the balloon inflated and pulled up against the abdominal wall can help temporize excessive bleeding while a cut-down or laparoscopic suturing of the vessels is completed. This is rarely necessary for the laparoscopically adept surgeon. The easiest and most efficient endoscopic means is the fascial closure device or the Carter-Thomason CloseSure System. A figure-of-eight suture is passed under vision, and control of the injured vessels is performed. Visual confirmation is perfomed in a reliable fashion without the need for extending the port incisions. This technique is superior to attempts at placement of fascial sutures in these small trocar incisions.

Injury to Major Vessels

Major vessel injuries are the most feared complications, and training centers have developed a simulation-based system for trainees to expose them to such stressful situations and potential management options (Veneziano et al., 2016). Avoiding major vessel injury is the mainstay of reducing the accentuated morbidity associated with these incidents. Most of the time, these vessels cannot be ligated because of a lack of collateral circulation, and repair is mandated commonly through an open conversion. Some major vessel injuries can occur at the time of initial trocar insertion. Here care must be taken to ensure that the skin incision for the trocar is wide enough to avoid forceful entry. To adequately visualize when major bleeding is suspected, it is important to leave the trocar or Veress needle in place and to place accessory ports if the patient is stable. In many occasions, conversion to open surgery through a midline incision when possible is appropriate. The offending trocar should be left in place until open conversion as it may be contributing to partial occlusion and tamponade of the bleeding. During robotic surgery, if the bleeding is successfully and instantly temporized with the robotic Prograsp forceps, the other two robotic arms can aid in investigating the extent of injuries along with bedside suctioning. Repair can be attempted, or a rescue polyglactin suture on a computed tomography-1 needle with a Hem-o-lok polymer locking ligation system at the other end can be used to aid in fixing the injury. The suture is pulled up, and the Hem-o-lok will tent the vessel wall up and temporize the bleeding until the subsequent throw of the suture is accomplished. A computed tomography needle is used as it allows for a bigger target to identify the needle in a puddle of blood, which can often result after major bleeding laparoscopically.

If the vessel in question is the internal iliac or inferior mesenteric vessel, ligation may be possible given the presence of a good collateral circulation. Superior mesenteric artery injuries warrant repair universally as the flow through this axis cannot be compensated through other vessels, and devastating complications like bowel necrosis and death ensues. Immediate conversion to open and vascular consultation is mandatory. Retroperitoneal hematomas are a special situation when major vessel injuries are suspected. In such occurrences, if the patient is hemodynamically stable and the hematoma is not expanding, observation and conservative management is a reasonable choice, and the decision to continue or abort the procedure should be made based on its urgency. The surgeon should not carry dissection of the retroperitoneal space in cases of a confined hemorrhage. In other situations of hemodynamic instability or a rapidly expanding hematoma, open conversion is mandated to repair aortic, vena caval, or external iliac artery injuries. Pneumoperitoneum can substantially help in repair of venous tears by increasing the intra-abdominal insufflation to 20 mmHg. This usually decreases venous bleeding while suturing is carried out quickly to avoid gas embolism at such pressures before dropping the pressure to 12 to 15 mmHg as soon as possible. In a similar fashion, external iliac vein tear suturing can be safely achieved by increasing pneumoperitoneum and turning off the sequential compression devices. This allows for decompression of the iliac vein empty, thus permitting controlled repair of the injury. In addition, during robotic surgery efficient use of the fourth arm for clamping and holding tension and pressure affords more control than conventional laparoscopy during challenging vascular suturing (Fig. 17.16). The use of novel sealing devices such as vessel-sealing devices, ultrasonic shears, or bipolar robotic coagulation cannot be emphasized enough when carrying delicate dissections around major structures.

Vascular complications in laparoscopic and robotic urologic surgery. In: Ghavamian R, ed. *Complications of laparoscopic and robotic urologic surgery.* 1st ed. New York, NY: Springer; 2010:45–58.)

Stapler Malfunction

With the wide use of staplers across United States that coincides with the increased use of minimally invasive surgery, reports of staple malfunction have increased. A reported rate of malfunction around 1% has become universally accepted. In an early FDA report on stapler use over approximately 10 years, 112 related deaths were reviewed that were mostly related to staplers firing improperly or staple lines rupturing or forming inadequately (Brown and Woo, 2004). Recalls on stapling devices are more common mostly for broken components or sterility issues. Overall, there appears to be underreporting of stapler incidents as evidenced by the results of a recent survey sent to program directors revealing that most have experienced laparoscopic linear stapler malfunction at some point. In this report, 25% of the time there was a drastic change in the course of the operation to staple-related issue (Kwazneski et al., 2013). In urologic surgery, the most common use of staplers is on vascular pedicles of different organs, especially on the renal hilum. Prevention is key in this setting. This involves careful inspection of the stapler while unpacking, precise loading of the cartridges, and judicious application of the stapler on vascular structures. The most common cause of staple malfunction is when the structure to be stapled is too thick for proper application. The surgeon should adequately dissect the vessels for staple application. When applying the staple, the full length of the jaw and the end point of the stapler jaw must be completely visualized before firing. When applying it to the renal hilum and when there is no evidence of tumor thrombus in standard laparoscopic radical nephrectomy, the stapler must be applied closer to the kidney, allowing a portion of the renal vasculature below the stapler to still be exposed for a second "rescue" stapler to be applied below, in case of a jammed stapler (Fig. 17.17).

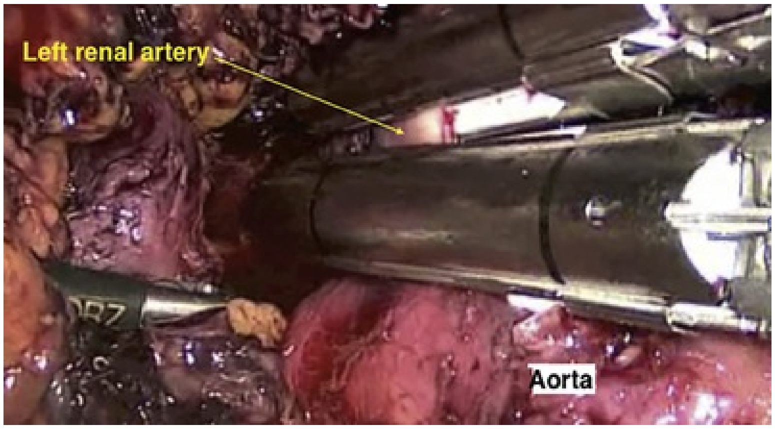

FIG. 17.17 The upper stapler is jammed during a laparoscopic left radical nephrectomy for a large renal mass. A second "rescue" stapler is manipulated under the jammed stapler for control of the artery.

Although some utilize Hem-o-lok clips for control of renal vasculature, most surgeons employ stapling devices as they ensure a more reliable means of control without the fear of dislodgement. Hem-o-lok or standard titanium clips can interfere with staple application if trapped in the stapler jaws, impeding the stapler and "jamming" the staple mechanism. One additional recommendation is the avoidance of excessive pressure and force on the handle, as this would overcome the safety lockout mechanism increasing the risk for malfunction.

Additional reviews of the FDA database do not conclude to the safety of one device over another for hilar control during nephrectomy, and incidents have been reported while using titanium clips, locking clips, and staplers. In locking clips, dislodgement has been reported as the leading cause of failure in 44% of cases. In titanium clips, difficulty closing or cutting and problems with jamming and the clip deployment device in automatic clip appliers were responsible for 26% and 27% of accidents, respectively. Although stapler lockup can be observed in 29% of associated incidents and staple line malformation in 44% of failures, rescue techniques can be quickly achieved with applying extra clips overlying the staple line or under the transection line (Hsi et al., 2007).

Postoperative Vascular Complications

Postoperative vascular complications can occur most frequently as a result of unrecognized bleeding at the time of surgery. This can be caused by complete or partial transection of an artery or vein. Arterial injuries usually are associated with a more rapid decrease in postoperative hematocrit and hemodynamic instability. On the contrary, venous bleeding is usually associated with a smaller bleeding vessel, is more self-limiting, and can present on a later postoperative day. Inadvertent ligation of major arteries leads to infarction of the target organ and hence delayed presentation of the injury. **Vascular complications account for the majority of early postoperative complications, especially in laparoscopic surgery** (Yaycioglu, 2005). In laparoscopic and robotic surgery, the presence of pneumoperitoneum temporarily tamponades small venous bleeding, leading to a delayed hemorrhagic presentation. Delayed presentation of vascular injuries in laparoscopy is especially concerning given the limited view of the laparoscope at any given moment. Injuries can occur anywhere along the shaft of the instruments or on entry and exit of the laparoscopic instruments and suction devices.

Some postoperative vascular complications are specifically worth mentioning as they pertain partial nephrectomy. Most hemorrhagic complications after partial nephrectomy occur after the patient has been discharged (Ramani et al., 2005). Iatrogenic vascular lesions after minimally invasive partial nephrectomy are rare occurrences generally seen 2 to 3 weeks postsurgery. The incidence is reported to be 2.0% to 2.7% (Hyams et al., 2011). These consist of arteriovenous (AV) fistulae and pseudoaneurysms, with the latter being more frequent. A recent systematic review and comparative analysis of 5229 patients who underwent open and minimally invasive partial nephrectomy was conducted. The incidence of pseudoaneurysm after open versus minimally invasive partial nephrectomy was 1.0% and 1.96%, respectively (Jain et al., 2013). AV fistulae and pseudoaneurysms form when segmental arteries and veins that are in close proximity in the tumor resection bed are injured on resection or suture repair. The deeper the tumor and the resection, the higher the chance is for these complications. Therefore patients with a higher nephrometry score can potentially be at higher risk for these complications (Chen et al., 2018). The risk for iatrogenic vascular lesions may be achieved by early unclamping as described in some robotic series related to a shorter ischemia time, especially if no arterial bleeding is present (Kondo et al., 2015). AV fistulae and pseudoaneurysms can exist alone or coexist. Several technical considerations can be undertaken to decrease the chance for AV fistulae or pseudoaneurysms. Careful inspection of the resection bed and suture ligation of larger segmental branches is advised. Often, a running absorbable suture through the tumor crater with careful needle passes, selectively suturing obvious vessels can aid in prevention. Sutures in the parenchymal repair should not be placed too deeply to avoid segmental branch injury (Tare et al., 2010).

Diagnosis and Management

The diagnosis is usually made in the immediate postoperative period with a precipitous decline in hematocrit. The presence of hematuria is a further alarming finding that would prompt radiologic evaluation. Renal pseudoaneurysms can be asymptomatic in up to 10% of cases, and these will be discovered on follow-up imaging studies. Some have suggested the use of selective enhanced computed tomography after partial nephrectomy in the early postoperative period to detect asymptomatic pseudoaneurysms. In a study of 117 patients who underwent computed tomography routinely on postoperative day 4, Takagi et al. reported a 15% detection rate. Only one patient had a hemorrhagic complication in the early postoperative period and was symptomatic. Patients with pseudoaneurysms less than 2 to 4 mm had spontaneous resolution (Takagi et al., 2014). Reports of presentation as enhancing lesions mimicking local recurrence or an avidly enhancing lesion in the arterial phase of a computed tomography scan have also been made (Campbell et al., 2016; Lonergan et al., 2016). When computed tomography appearance is equivocal, renal angiography will ultimately aid in the definitive diagnosis (Schommer et al., 2017). Most patients will present with fever, gross hematuria, flank pain, hypotension, bloody discharge from the drain site, dizziness, and syncope. A minority will have an acute major bleed and will require emergent embolization. This is especially true in case of multiple pseudoaneurysms in the same kidney, a scenario that can occur (Gupta et al., 2017). **When patients present with these symptoms, especially with a history of a recent partial nephrectomy, a high index of suspicion for a pseudoaneurysm should be present. In this case, many**

advocate a direct evaluation with arterial angiography, bypassing the computed tomography. This is to avoid an additional contrast load to the patient who might be anemic and intravascularly depleted, and also has mild renal compromise. It also is a more expeditious approach when the index of suspicion is high.

If pseudoaneurysms are incidentally detected on imaging obtained for other reasons, conservative management is an acceptable approach in the absence of gross hematuria, decreased hematocrit, and hemodynamic instability (Darbyshire et al., 2014). Serial monitoring of the hematocrit and hemodynamics is sufficient. When suspected with a documented decline in hematocrit, especially when the patient presents in a delayed fashion after discharge, computed tomography is indicated (Fig. 17.18). This reveals a characteristic blush in the arterial phase. After initial diagnosis using computed tomography with intravenous contrast and if hemodynamic instability exists and there is a precipitous decline in hematocrit, angiography and selective embolization of the bleeding vessel is indicated. This is the treatment of choice for pseudoaneurysms and AV fistulae (Fig. 17.19). If unsuccessful, the next step is surgical intervention. In a recent study with long-term follow-up of up to 10 years, technical success rates nearing 100% were frequently reported in the literature using super selective branching microcoil embolization (Strobl et al., 2016). Although parenchymal volume loss up to 25.2% was observed, the impact of embolization on renal function and estimated glomerular filtration rate (eGFR) did not appear to be detrimental.

Bowel Injuries

Incidence and Presentation

Bowel injuries can occur during major and minor open urologic procedures, and early recognition and repair is of paramount importance. The exact incidence of bowel injuries is difficult to ascertain. There is an underreporting of bowel injuries, as some are minor lacerations or serosal tears that do not interfere with the course and outcome of the operation. Intraoperative injuries that are missed can present with ileus, abdominal pain, leukocytosis, and sepsis, with major associated morbidity and mortality risk. Minimally invasive procedures present their own unique set of challenges in both the diagnosis and management of bowel injuries. With the increased utilization of minimally invasive laparoscopic and robotic procedures in urology, familiarity with presentation and management of these complications are of paramount importance. The mechanism of injury is also unique. Injuries that are detected intraoperatively can be managed accordingly. The reported incidence is established to be well below 1%, at approximately 0.2% What is unique about laparoscopic surgery is that delayed presentation of bowel injuries during laparoscopy or robotic surgery can carry devastating consequences including fever, abdominal pain at trocar site, generalized peritonitis, sepsis, and death (Van der Voort et al., 2004). Up to 69% of bowel injuries were not recognized intraoperatively and were found to occur any time from access and entry of the abdominal cavity to exit. In a classic manuscript on laparoscopic bowel injury, Bishoff et al. described their incidence and clinical presentation (Bishoff et al., 1999). **Delayed and unrecognized bowel injury has an atypical presentation after laparoscopic surgery. Classically, patients can present with absence of peritonitis, acute abdomen, or leukocytosis. Symptoms typically occur within 24 to 48 hours after surgery. Symptoms include single trocar site pain disproportional to the examination with no purulence, abdominal distension, ileus, and diarrhea. Complete blood count usually reveals leukopenia rather than leukocytosis** (Bishoff et al., 1999). When suspected, computed tomography of the abdomen and pelvis is warranted (Fig. 17.20). This is best obtained with oral and intravenous contrast with delayed images. If a rectal injury is suspected, rectal contrast is also preferred. **A complicating factor after laparoscopy is the presence of intra-abdominal gas, which can be expected up to 7 days**

postoperatively. Although some patients can still present with frank peritonitis, acute abdomen, and classic symptoms, a high index of suspicion for atypical presentation should exist after laparoscopy. Tackling more complicated cases with minimally invasive surgery accounts for the increased incidence of bowel injuries to 0.75% reported by Schwartz et al. from 0.65% in the previous decade. The rate of unrecognized injuries peroperatively decreased dramatically from 70.4% to 36.9% despite extensive adoption of laparoscopic surgery (Schwartz et al., 2010). Whether this reflects better awareness of surgical complications associated with laparoscopy or enhanced minimally invasive technologies such as sealing devices is yet to be determined, as multiple factors can effectively play a role.

Mechanisms of Injury

The mechanisms of bowel injury could be caused by poor technique in trocar insertion, Veress needle injuries, mechanical injuries resulting from exaggerated retraction, and tissue handling and electrocautery injuries. Trocar-associated injuries share similarities with instrument insertion–associated injuries. In fact, 21% of trocar access–related injuries were shown to be bowel injuries based on an FDA report, with some resulting in patient death. Extreme caution must be exercised when deciding which location to gain initial abdominal access for insufflation. **If a patient has a midline scar and previous abdominal operation, the position of the initial Veress needle should be in an alternative location in the abdomen away from that scar.** In many instances, bowel adhesions to the anterior abdominal wall can exist in sites well away from the abdominal incision. Here, the use of optical trocars and the open Hasson technique can decrease the chance for bowel injury. Most bowel injuries that occur as a result of Veress needle injuries are small bowel injuries**. The saline drop test examination is helpful to ascertain proper positioning of the Veress needle. After initial partial insufflation, the Veress needle must be able to be advanced 1 to 2 cm with no resistance.** This usually (but not always) denotes correct intraperitoneal position of the Veress. Once the Veress needle is in and the original camera trocar is inserted, it is imperative to check the peritoneal cavity for adhesions. The location of the anticipated following trocars must be devoid of bowel adhesions to the anterior abdominal wall. Complete insufflation is necessary to avoid tenting of the peritoneal lining and forceful uncontrollable insertion of the trocars. **The surgeon should consider a bowel prep for difficult cases or for patients with a history of extensive prior abdominal surgery. Lysis of adhesions can be carried out with cold laparoscopic scissors with no electrocautery to avoid thermal spread and delayed thermal injuries.** If bowel manipulation is necessary and lysis of adhesions is performed, careful attention to counter traction on the bowel prevents mechanical shear and denudation injuries. This is also true in robotic surgery, when careful manipulation of the bowel is even more paramount because of the absence of haptic feedback and the strong constant grasping force of the robotic prograsp instrument. Extensive lysis of adhesions is ill-advised away from the surgical field. As such, enough is required to allow the surgical field in focus to be accessed safely. Extensive “sweeping” maneuvers are also discouraged laparoscopically and robotically as these can lead to partial thickness and full-thickness denudations and bowel injuries. Mechanical bowel injuries occur when instruments are inserted blindly outside their safe range of motion. The injuries can involve abrasion, compression, and sharp wounds. Investigating the extent of injury is key. Often multiple bowel injuries can coexist, and this will guide the subsequent primary repair of bowel resection. It is of utmost importance at the start of the case and upon access of the abdomen to maximize the range of motion of instruments by lysis of adhesions and dissecting out the operative space wide enough to allow maximum safety (Venkatesh and Landman, 2006). **On occasion, extensive adhesions exist that may be prohibitive to safe intraperitoneal laparoscopic and robotic surgery. In these circumstances, open conversion may be the most prudent maneuver to prevent complications.**

Bowel injuries can be divided into early intraoperative injuries detected at the time of surgery and delayed injuries detected after the operation is completed. Most intraoperatively detected injuries can be managed intraoperatively, mostly with direct suture repair. Most injuries to the small bowel are direct perforations or serosal injuries. Both can be reliably repaired intraoperatively. Limited colonic injuries in the absence of major fecal spillage can also be repaired intraoperatively, open, laparoscopically, or robotically. Major bowel injuries that involve extensive lacerations or mesenteric injuries that leave a questionably viable bowel segment can be managed with bowel resection. A general surgical consultation is usually advisable. For an extensively diseased bowel, an end ileostomy and subsequent reconstitution of the intestinal tract may be advisable. Most extensive bowel injuries are managed with resection and primary stapled anastomosis. In the case of an extensive colonic injury with obvious fecal soilage, a colostomy may be required. Copious irrigation is necessary, and broad-spectrum antibiotics should be administered.

Most delayed presentations of bowel injury are caused by thermal injuries secondary to excessive and incorrect use of electrocautery. Monopolar electrocautery could be a dangerous energy modality in laparoscopic and robotic surgery. In one study, critical heat spreads of greater than 20 mm were found with monopolar devices used for 2 seconds at 60 watts. The use of bipolar energy significantly reduces thermal spread and should be the cautery modality of choice. Mean thermal spreads of 3.5 mm, 2.2 mm, 1.3 mm, and 2.8 mm were demonstrated for robotic hot shears, bipolar instruments, harmonic devices, and Ligasure devices, respectively (Hefermehl et al., 2013). **Stray electrosurgical current can be caused by poor technique or an insulation defect in the instrument resulting in direct or capacitative coupling with metal trocars.**

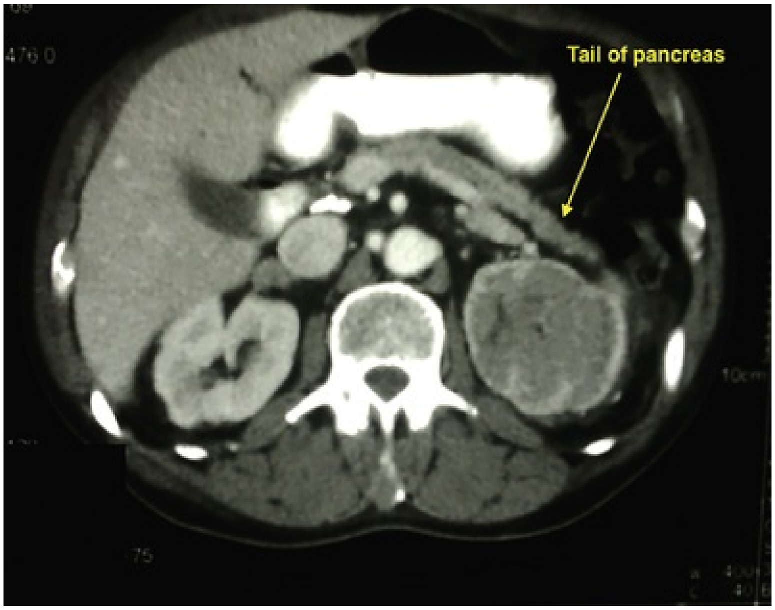
Maneuvers should be employed to prevent electrosurgical injuries. Judicious use of monopolar electrocautery should be employed. Most laparoscopic procedures should be performed with controlled sealing and shearing instruments such as harmonic scalpel or vessel-sealing devices. In robotic surgery, monopolar cautery is an important energy source that is still continuously employed on the dissecting scissors. As such, judicious application is mandatory. The surgeon should ensure that all bowel structures are away from the tip of the instrument for minimizing thermal spread. Instruments with thermal energy at the tip should be always in the field of vision. In laparoscopic surgery, the shaft of all instruments should be inspected before surgery so that no thermal injuries can occur along the shaft of the instrument out of the surgical field. The surgeon should inspect the surgical field on laparoscopic and robotic exit.

In robotic surgery, the console surgeon should be aware and directly visualize instrument introductions initially aiding the bedside assistant. The bedside assistant should exercise caution in gradual and slow instrument applications under direct vision before instrument memory on the robotic arm is achieved. The bedside assistant will have to be alert to any increased resistance when inserting a robotic instrument and needs to communicate with the console if resistance is encountered (Sotelo et al., 2016).

Conservative management of intraoperative thermal injury is ill advised. Most superficial bowel burns detected intraoperatively can be repaired with serosal Lambert sutures creating an extra serosal layer over the affected area of the bowel (Mert, 2015). When extensive burns are encountered, debridement and repair are mandatory with primary closure. Caution should be exercised as thermal spread could be beyond the level of the obvious serosal discoloration, and at times, a bowel resection and anastomosis with a formal open conversion may be necessary. Help from general surgery is advised when the initial repair does not seem to be optimal or a bowel diversion is sought.

Duodenal and Pancreatic Injuries During Nephrectomy

The duodenum is at risk for injury during right open, laparoscopic, and robotic renal procedures as kocherization of the duodenum is necessary for exposure of the renal hilum. Direct shearing or puncture injuries are encountered. Very minor trauma to any part of the duodenum leads to perforation, even when they are less than 5 mm with delayed presentation of fever, abdominal pain, and possible sepsis. Duodenal wall hematomas are another feared complication that could occur by compression. These hematomas can lead to prolonged obstructive ileus, demanding extended bowel rest, total parenteral nutrition, and lengthy hospital stay (Joshi and Sundaram, 2013). During left nephrectomy, similar attention should be paid to the tail of the pancreas, which is in close proximity to the upper pole of the left kidney and also the adrenal gland (Fig. 17.21). **Pancreatic injury is often associated with multiple complications related to uncontrolled pancreatic exocrine secretion, including pancreatic fistula, pseudocyst, and intra-abdominal abscess. Somatostatin analogues such as octreotide have been shown to decrease pancreas-related morbidity after major pancreatic resection in patients with pancreatic neoplasms and acute severe pancreatitis.** In one study, empirical use of octreotide for patients with pancreatic injury was questioned as patients treated with octreotide had a higher rate of fistula formation (48% vs. 40%), longer duration of fistula drainage, and longer hospital stay compared with untreated patients (Nwariaku et al., 1995). When obvious injury is encountered, distal pancreatectomy is employed intraoperatively. **Delayed presentation of pancreatic injury can occur postoperatively. Increased clear fluid drainage from the drain site and increased amylase in the drain fluid can be diagnostic.** Computed tomography is necessary to ensure that there are no large undrained collections. Additional drains can be placed as needed. In patients with no drains in whom the pancreatic injury was not detected intraoperatively, postoperative management includes percutaneous drain placement and somatostatin. The patient will need to be on bowel rest, nasogastric suction, and nutritional support (Debi et al., 2013). When drainage does not subside, distal pancreatectomy may be necessary.



FIG, 17.21 Axial computed tomography image revealing the proximity of the tail of the pancreas to the upper pole of the kidney with a large upper pole mass.

Rectal Injury

Rectal injuries are a feared complication of difficult prostatectomies. With the advent of robotic prostatectomy, they remain a complication that is a concern during the learning curve of the operation. It is the most common bowel complication in radical prostatectomy. Significantly higher rectal injury rates have been reported for laparoscopic radical prostatectomy (1.0%) versus robotic radical prostatectomy (0.3%) and open radical prostatectomy (0.5%) (Tewari et al., 2012). **The incidence of rectal injury is the same for open and robotic prostatectomy, but the risk is higher in salvage prostatectomy.** In a recent review of 24,178 patients, the incidence of rectal injury was 0.47% for patients who underwent open or robotic prostatectomy and 6.86% for patients undergoing salvage prostatectomy. Besides salvage prostatectomy, local tumor stage, Gleason grade, lymph node status, and surgical experience, but not surgical approach (robotic vs. open), could be identified as risk factors for rectal injury in univariate and multivariate analyses (Mandel et al., 2018).

A higher level of experience and expertise is needed for salvage radical prostatectomy as rectal injury in this subgroup is reported to be around 6.8% in some series (Yuh et al., 2014, Mandel et al., 2018). In these complex cases, the risk for fistula formation is real. The overall incidence of rectoanastomosis fistula after radical prostatectomy in general is less than 0.1%. The extent of rectal laceration, prior radiation, and intraoperative signs of rectal infiltration are associated with development of a subsequent recto-anastomosis fistula (Mandel et al., 2018).

Surgery after transurethral resection of the prostate gland, microwave thermotherapy, or recurrent prostatitis is among other scenarios after which radical prostatectomy could be challenging. The intense fibrosis and changes in periprostatic tissues account for most of the difficulties encountered during surgery. The most common site of rectal injury in robotic prostatectomy is near the apex during a posterior dissection. Care should be taken to avoid electrocautery while dissecting on the anterior rectal wall as the posterior aspect of the prostate is dissected off the rectum. In cases in which intense fibrosis or difficulty in dissection is encountered, as in salvage prostatectomy, placement of a rectal EEA dilator may help in identification of the rectum. In salvage prostatectomies, consideration should be given to a modified bowel preparation in case a rectal perforation is encountered.

Management

Management consists of primary repair versus delayed repair and colostomy. **In the absence of gross fecal spillage, primary closure might be possible. This can be achieved with multilayer nonoverlapping sutures.** The rectal mucosa and serosa are closed with absorbable sutures. The perirectal tissues for bolstering the repair are closed with nonabsorbable sutures. The edges being sutured should be well-debrided and well-vascularized and approached tension-free. Usually, a two-layer repair can be performed approximating the lateral edges over the sutured repair (Yuh et al., 2014).

The integrity of the repair is assessed with a bubble test, which involves injecting air in the rectum through a Toomey syringe or a rectal tube while observing for air bubbles in the surgical field. Consideration is given to an omental or fat interposition if necessary and possible. A postoperative drain is mandatory. **Although minor rectal lacerations in a preoperatively prepped rectum can be repaired primarily, most moderate to extensive rectal injuries after salvage prostatectomy after radiation therapy are best managed with a diverting colostomy.** Postoperatively, a low-residue diet and broad-spectrum antibiotics are advised for 3 to 7 days.

Unrecognized rectal injuries can present in the immediate postoperative period. Depending on whether the procedure was open or robotic, leukopenia or leukocytosis can be present. Other symptoms include nausea, vomiting, ileus, focal pelvic pain lateralizing to one side, or frank peritonitis with an acute abdomen. Prompt evaluation with computed tomography of the abdomen and pelvis with rectal contrast or gastrograffin enema is usually enough to assess the injury and guide therapy. Surgical exploration with copious irrigation and diverting colostomy is usually the surgical procedure of choice to decrease the chance for sepsis and subsequent rectourethral fistula formation, because of the proximity of the urethrovesical anastomosis.

Port Site Hernia

The incidence of port site hernia in recent reviews ranges from 0.3% to 5.4%. Other factors identified in affecting port site hernia development include but are not limited to older age, previous hernia, operative time, and trocar size (Hussain et al., 2009). It presents usually as a painless bulge in mostly extraumbilical ports. The diagnosis can be confirmed by computed tomography (Fig. 17.22). The mean time to presentation is 9.6 days (1 to 54 days). It is more common in 12-mm trocars compared with 10-mm trocars (3.1% vs. 0.23%, respectively) (Kadar et al., 1993). Judicious use of trocars and the use of 5-mm trocars when sufficient can decrease the incidence of port site hernias. Recently, bladeless trocars are more commonly used. The fascial defect for a bladeless trocar is significantly smaller than for a bladed trocar of the same size (Pereira et al., 2016). Despite this, hernias associated with the use of 12-mm bladeless trocars have been reported in the literature (Park et al., 2012). A robotic 8-mm port off the midline would benefit from additional inspection as larger than expected fascial incisions can ensue secondary to excessive arm movements or extreme rotational maneuvers of the associated robotic arm. Although potentially offering greater patient cosmetic satisfaction, single-incision laparoscopic surgery (SILS) and laparoendoscopic single-site surgery (LESS) were associated with an increased incidence of incisional hernias (Buckley et al., 2016). In fact, larger incisions are required to accommodate multiple trocars through the access site, and many reviews suggest a higher incidence of umbilical hernia after single platform surgery at this anatomic site (Agaba et al., 2014).

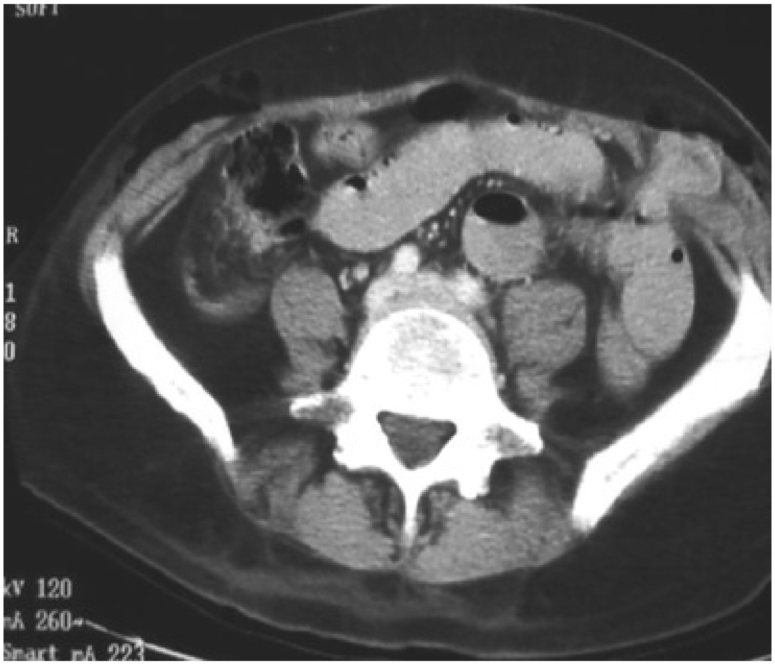


FIG. 17.22 Computed tomography image revealing a right lower quadrant port site hernia.

Closure of large fascial defects on the trocar sites with a single figure-of-eight absorbable suture with a fascial closure device will often suffice. In case of delayed presentation of a symptomatic or cosmetically unappealing port site hernia, most can be repaired laparoscopically or robotically with mesh interposition with excellent outcomes (Fig. 17.23).

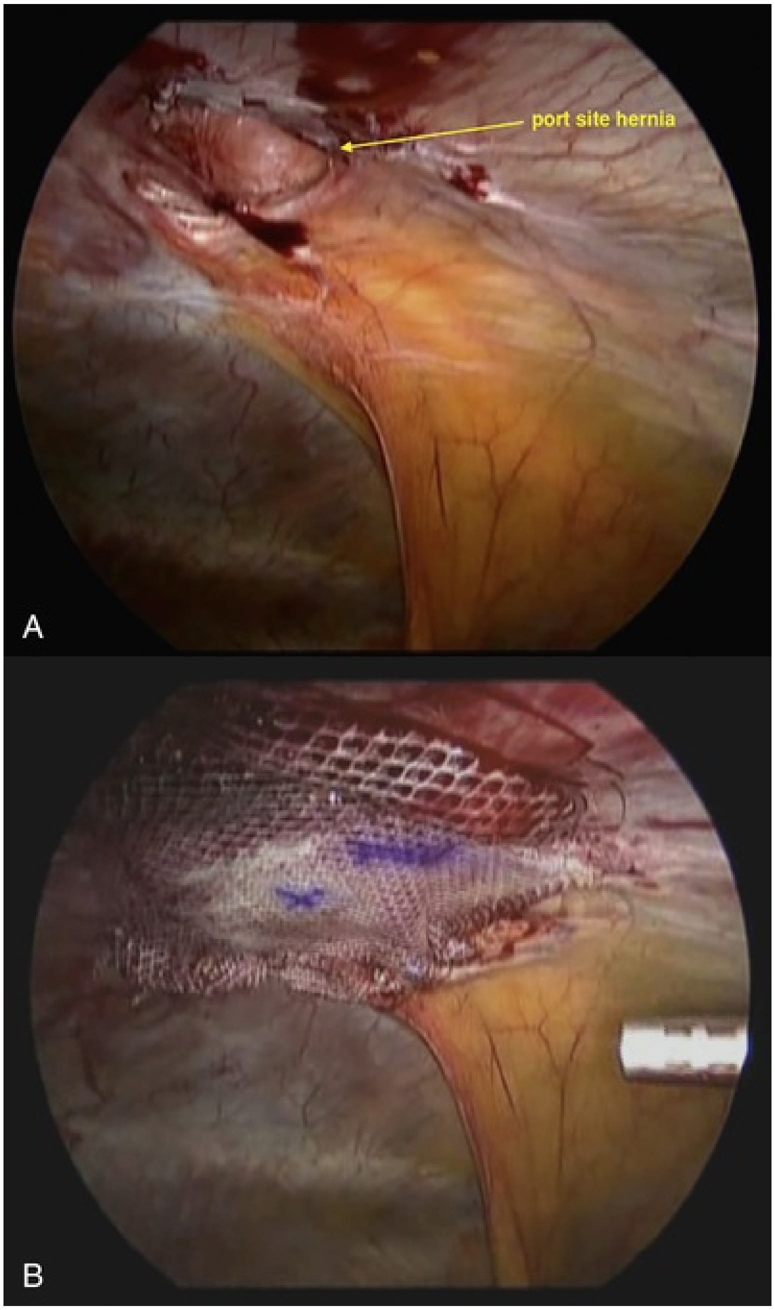

FIG. 17.23 (A) Laparoscopic view of a port site hernia. (B) Laparoscopic repair with mesh.

Venous Thromboembolism

The risk for venous thromboembolism (VTE) is increased with pelvic surgery, malignancy, obesity, and increased surgical times. Laparoscopic and robotic operations are on average longer than their open counterparts, especially during the initial learning curve of the surgeon. One might expect that the reverse Trendelenburg position and pneumoperitoneum (increased return from the legs) can create venous stasis and possibly increase the risk for DVT). Some have suggested that there is no evidence of increased incidence of DVT after laparoscopic surgery (Abdel-Meguid and Gomella, 1996). The true incidence of DVT and pulmonary embolism (PE) is not well known after laparoscopic urologic surgery. Secin et al. reported on a multi-institutional study of symptomatic DVT and PE after laparoscopic and robotic radical prostatectomy. Of the 5951 patients, 31 (0.5%) developed symptomatic VTE, 22 (71%) had DVT only, 4 had a PE without an identified DVT, and 5 had both a PE and DVT. Two patients died of PE. Smoking, large prostate size, patient re-exploration, longer operative times, and longer hospital stays were associated with VTE (Secin et al., 2008). A recent study addressed VTE after major urologic oncologic surgery with a focus on the incidence and timing of VTEs after 27,455 operations (Alberts et al., 2014). This was an American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) study from 2005 to 2012. The risk for VTE for radical nephrectomy, partial nephrectomy, and radical nephroureterectomy was 1.1%. The risk for VTE in minimally invasive radical and partial nephrectomy was 0.7%. The risk for VTE after radical prostatectomy and radical cystectomy was 1.1% and 5.5%, respectively. The majority of VTEs occurred after discharge (82.6% after radical prostatectomy) (Alberts et al., 2014).

There are no consensus guidelines for VTE prophylaxis, and its utilization is variable. One recent population-based study of nationwide practices of 94,709 men who underwent radical prostatectomy was published. In this study, 52.2% used mechanical VTE prophylaxis only, 7.2% used pharmacologic prophylaxis, 10.6% used a combination of the two, and surprisingly 30% used no VTE prophylaxis (Weinberg et al., 2014). Patient- and procedure-specific risk factors also must be taken into account. It is important to adhere to local hospital policies on VTE prevention and prophylaxis. Data regarding thromboprophylaxis remains sparse to date, and current therapies employed depend mostly on local hospital policies to help assess the patient's risk factors and predisposition for DVT development. In an AUA best practice statement for the prevention of DVT released in 2009, patient risk stratification was introduced based on clinical characteristics of the patient and procedure being performed (Forrest et al., 2009). This helped identify patients at high risk for DVT development (e.g., age older than 60 years, prior thromboembolic events, cancer, hypercoagulable state) in whom pharmacologic prophylaxis is mandatory.

Older age, previous VTE or family history of VTE, presence of malignancy or obesity, and inherited or acquired coagulable states are risk factors. It is important to risk-stratify patients for their individual risk. There are no universally accepted method of VTE risk assessment. **The most widely used method for risk stratification is the Caprini score, modified by The American College of Chest Physicians** (Caprini, 2010; Gould et al., 2012). The system assigns an appointed value to each risk factor according to the relative risk for VTE based on the literature. The points are then totaled for a score (Table 17.2). **Patients are classified as very low risk (score 0), low risk (score 1 to 2), moderate risk (score 3 to 4) and high risk (score ≥5)** (Table 17.3). This model is validated and can be applied to patients undergoing urologic surgery.

TABLE 17.2

The Caprini Risk Assessment Model

1 POINT	2 POINTS	3 POINTS	5 POINTS
Age 41–60 y	Age 61–74 y	Age ≥75 y	Stroke (<1 mo)
Minor surgery	Arthroscopic surgery	History of VTE	Elective arthroplasty
BMI >25 kg/m^2	Major open surgery (>45 min)	Family history of VTE	Hip, pelvis, or leg fracture
Swollen legs	Laparoscopic surgery (>45 min)	Factor V Leiden	Acute spinal cord injury (<1 mo)
Varicose veins	Malignancy	Prothrombin 20210A	
Pregnancy or postpartum	Confined to bed (>72 h)	Lupus anticoagulant	
History of unexplained or recurrent spontaneous abortion	Immobilizing plaster cast	Anticardiolipin antibodies	
Oral contraceptives or hormone replacement	Central venous access	Elevated serum homocysteine	
Sepsis (<1 mo)		Heparin-induced thrombocytopenia	
Serious lung disease,		Other congenital or	

including pneumonia (<1 mo)		acquired thrombophilia	
Abnormal pulmonary function			
Acute myocardial infarction			
Congestive heart failure			
History of inflammatory bowel disease			
Medical patient at bed rest			

BMI, Body mass index; *min,* minutes; *mo,* month; *VTE,* venous thromboembolism; *y,* year.

TABLE 17.3

Recommendations for Thromboprophylaxis in Various Risk Groups

RISK AND CONSEQUENCES OF MAJOR BLEEDING		
RISK FOR SYMPTOMATIC VTE	**AVERAGE RISK (~1%)**	**HIGH RISK (~2%) OR SEVERE CONSEQUENCES**
Very low (<0.5%)	No specific prophylaxis	No specific prophylaxis
Low (~1.5%)	IPC	IPC
Moderate (~3.0%)	LDUH, LMWH, *or* IPC	IPC
High (~6.0%)	LDUH or LMWH *plus* IPC	IPC until risk for bleeding diminishes and pharmacologic prophylaxis can be added
High-risk cancer surgery	LDUH or LMWH *plus* IPC and extended duration prophylaxis with LMWH postdischarge	IPC until risk for bleeding diminishes and pharmacologic prophylaxis can be added
High risk, LDUH an LMWH contraindicated or not available	Fondaparinux *or* low-dose aspirin (160 mg); IPC; or both	IPC until risk for bleeding diminishes and pharmacologic prophylaxis can be added

LDUH, Low-dose unfractionated heparin; *LMWH,* low–molecular-weight heparin; *IPC*, intermittent pneumatic compression; *VTE,* venous thromboembolism.

From Gould MK, Garcia DA, Wren SM, et al.; American College of Chest Physicians: Prevention of VTE in nonorthopedic surgical patients: Antithombotic therapy and prevention of thrombosis, 9th ed: American College of Chest Physician Evidence-Based Clinical Practice Guidelines. *Chest* 141(2 suppl):e227S–e277S, 2012.

In the majority of patients, DVT prophylaxis comprises mechanical prevention (i.e., early patient ambulation, intermittent pneumatic compression) and pharmacologic prevention (i.e., low–molecular-weight heparin or, less commonly, other agents such as unfractionated heparin).

Procedure-specific criteria for thromboprophylaxis are important considerations. General recommendations are tabulated in Table 17.3. **Very low-risk procedures require early and frequent ambulation.** This includes most transurethral and anti-incontinence procedures in which graduated compression stockings can be used as a safety measure. **In low-risk settings, mechanical prophylaxis with intermittent pneumatic compression or graduated compression stockings is sufficient. In patients with moderate risk, pharmacologic prophylaxis, preferably with low molecular weight heparin, is recommended, although low-dose unfractionated heparin or fondaparinux is acceptable. High-risk and very high-risk patients can be managed with low-molecular-weight heparin, low-dose unfractionated heparin, or fondaparinux. In these patients with multiple VTE risk factors, a pharmacologic method may be combined with mechanical methods.** As opposed to minimally invasive surgery, in major open surgery a more aggressive regimen combining sequential compression devices and efficient pharmacologic prophylaxis is recommended for prevention of DVT.

The optimal timing of DVT prophylaxis is not well known. **It is generally agreed that mechanical methods should commence just before surgery and that pharmacologic agents should ideally be started 2 to 12 hours preoperatively.** Fondaprarinux can be administered 6 to 8 hours after surgery. In practice, for high-risk patients, pharmacologic prophylaxis with subcutaneous heparin can be started just before or during most urologic procedures with no major risk for bleeding. Initiation of pharmacologic prophylaxis within 48 hours of surgery was not associated with an increased risk for intraoperative bleeding (Murphy et al., 2016). The length of treatment is another important aspect to consider because risk for DVT persists for an extended period postoperatively (Jordan et al., 2017). **In most cases, VTE prophylaxis should continue until the patient is fully ambulatory.** There is tremendous disparity in the definition of fully ambulatory patients. Despite early ambulation and mobilization, patients are still at increased risk for VTE as the risk persists for weeks after full mobilization (Amin et al., 2010). For most patients, prophylaxis beyond discharge is not currently recommended. However, data exist that there is an associated benefit with extended prophylaxis in major abdominal/pelvic surgery for patients with cancer. A recent meta-analysis of four randomized trials of patients undergoing major abdominal or pelvic surgery compared extended VTE prophylaxis with low-molecular-weight heparin for at least 1 month postoperatively versus VTE prophylaxis administered only during the in-hospital period. Extended VTE prophylaxis reduced the rate of VTE from 14% to 6% and the rate of symptomatic VTE from 2% to 0.2% without increasing the risk for bleeding (Rasmussen et al., 2009). Finally, in patients with a contraindication to anticoagulants or those with a high risk for intraoperative bleeding, mechanical methods should be employed preoperatively, and pharmacologic agents can be started or added postoperatively when adequate hemostasis is achieved and considered safe.

Lymphoceles

Lymphoceles are the most common complication caused by disruption of lymphatic drainage after pelvic lymph node dissection. They are lymph fluid-filled collections without an epithelial wall lining along major vessels, commonly the iliac vasculature. Lymphoceles were first described almost 50 years ago by Basinger and Gittes (Lebeis et al., 2015). It remains unclear whether the introduction of robotic and minimally invasive surgery is associated with suboptimal lymphostasis. However, the transperitoneal approach to robotic prostatectomy has been thought to be associated with a lower rate of lymphoceles because of theoretical peritoneal reabsorption of lymphatic fluid. **However, lymphoceles can still occur after transperitoneal operations in the deep pelvis, especially after pelvic lymphadenectomy, as loculations and retroperitonealization can occur as early as 48 to 72 hours postoperatively.** Reported incidence rates differ because of the variability of lymph node dissection templates and because most lymphoceles are asymptomatic. Lymphocele rates can range from 4.6% when limited lymphadenectomy is performed compared with as high as 10% when an extended nodal dissection is performed by the same group (Briganti et al., 2006). Lymphocele rates after major urologic oncologic series are summarized in Table 17.3. The techniques of lymphostasis using clips or bipolar devices have also been analyzed when applied on the femoral lymphatic channels. There is no robust data to suggest the best approach, although some results support the use of clips (Stolzenburg et al., 2017). Recently, the robotic vessel sealer has been advocated as an excellent instrument for nodal dissection allowing for the sealing of lymphatic channels as they are encountered. The lymphatic channels are effectively sealed obviating the need for indiscriminate application of Hem-o-Lok clips or titanium clips.

Most patients with lymphoceles are asymptomatic, and an incidental diagnosis is made on routine imaging or imaging performed for other reasons. Generally, asymptomatic lymphoceles smaller than 5 cm should be managed conservatively. When very large symptomatic lymphoceles develop with subsequent compressive symptoms on the iliac vasculature resulting in lymphostasis and lower extremity edema, pressure on the bladder, urinary frequency, and urgency, percutaneous drainage is warranted. Patients with delayed presentation are diagnosed with cross-sectional imaging (Fig. 17.24). **If the lymphocele is thick-walled and especially when a lymphocele reaccumulates after prior percutaneous drainage, laparoscopic drainage and marsupialization with a peritoneal window is warranted.** Aspiration is not advised as re-accumulation inevitably occurs and there is a risk for introduction of bacteria and infection. Sclerotherapy with agents like povidone-iodine or doxycycline have been attempted but could make surgical laparoscopic marsupialization into a peritoneal window more complex if subsequently necessary. Lymphocele infection is a feared complication, and urine leaks should always be part of the differential diagnosis. Patients can present with fever, chills, and signs of sepsis when superinfection of a large lymphocele is suspected. Treatment includes intravenous fluids and broad-spectrum antibiotics with percutaneous drainage.

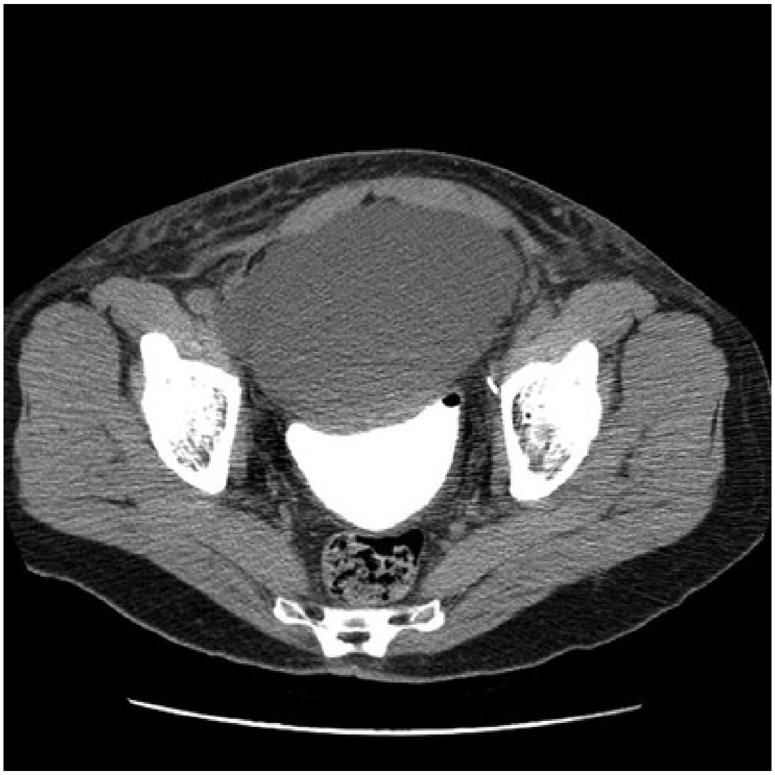

FIG. 17.24 Large lymphocele after robotic radical prostatectomy anterior to the bladder.

Inspection of the surgical field after pelvic lymph node dissection and radical upper tract surgery with or without lymphadenectomy is mandatory. Control of any apparent lymphatic vessels with clips and the use of bipolar sealing devices are crucial. Recently, use of adjunctive hemostatic agents such as fibrin sealants are advocated as an additional means for lymphostasis. Although designed for hemostasis, sealants can form a protective layer on lymphatic channels that run alongside smaller or large vessels, especially in the presence of minimal blood (Buelens et al., 2018). Preventive surgical techniques have been described to minimize the risk for lymphocele formation. Meticulous attention to detail during dissection is key. Lebeis et al. performed an interposition and fixation of the ipsilateral peritoneal flap on the bladder itself (Lebeis et al., 2015). Placement of a drain is advisable for most cases of major lymph node dissection, especially in the deep pelvis. The extraperitoneal or transperitoneal approach for radical prostatectomy does not seem to have any impact on the rate of symptomatic lymphocele formation in the current era of robotic surgery (Horovitz et al., 2017).

Conclusion

There is a wide array of complications that can occur in urologic surgery. The recent wide adoption of minimally invasive surgery, especially laparoscopic and robotic surgery, has introduced a new set of potential complications. With this, a new set of operative, diagnostic, and therapeutic skills are necessary to prevent, identify, and treat these complications. Although some complications are managed conservatively, many require medical and some require invasive intervention. Diagnostic and interventional radiology plays a crucial role in urologic complication detection and management. At times, minor or major operative intervention is needed. Although a high index of suspicion is key to the detection and diagnosis of a potential problem, prevention of complications remains the key to a more favorable surgical outcome. Judicious attention to patient selection, positioning, preoperative planning, and meticulous surgical technique is the hallmark of complication prevention.

Key Points

- A wide array of physiologic, urinary, vascular, bowel, and visceral complications can occur with all forms of urologic operations.
- With the wide adoption of laparoscopic and robotic surgery in urology, a unique set of complications is encountered.
- As more complex operations are performed in a minimally invasive fashion, the rate of complications can increase.
- Some complications after laparoscopic and robotic procedures can present in an atypical and delayed fashion.
- A high index of suspicion is necessary for prompt and timely intraoperative and postoperative diagnosis and management.
- The most important aspect of complication management is complication prevention with adequate planning, attention to detail, and meticulous surgical technique.

Urologic Considerations in Pregnancy

Melissa R. Kaufman MD, PhD

Physiologic Changes During Pregnancy

Pregnancy demands extensive adaptation to maternal anatomy, physiology, and metabolism. Such adaptations involve most organ systems, and basic understanding of these parameters will assist the urologist in determining the presence of pathology. This section outlines considerations that may affect treatment strategies for pregnant patients requiring urologic interventions.

Cardiovascular

Profound alterations in the cardiovascular system manifest during pregnancy to accommodate increased oxygen and nutrient demand from both the mother and fetus. Decreases in systemic vascular resistance caused by presence of the low-resistance placenta and vasodilation produced by progesterone and prostacyclin-mediated smooth muscle relaxation are evident even before uteroplacental circulation and represent the primary driver of subsequent cardiovascular alterations (Chapman et al., 1998). Resultant to such vascular resistance changes is a concomitant decrease in mean arterial pressure to an average of 10 mm Hg below baseline by the second trimester (Thadhani et al., 2001). Increases in sympathetic activity result in up to a 30% increase in maternal heart rate, which reaches a maximum at 20 weeks' gestation (Desai et al., 2004). Cardiac output (CO) is the product of stroke volume and heart rate, both of which increase as described earlier, thus pregnancy is accompanied by a massive CO increase beginning in early pregnancy and peaking on average at 30% to 50% above baseline preconception values (van Oppen et al., 1996). **In addition to the renal concerns outlined in the following section, it is critical for the urologic surgeon to consider the impact of positioning during surgical procedures with regard to maternal cardiac physiology.** CO in pregnancy is dependent on maternal position, and standard techniques for urology may pose unintended consequences. In the supine position, CO in the pregnant patient decreases by up to 30% at term compared with the lateral recumbent position (Clark et al., 1991). When supine, decreased blood return decreases stroke volume with a resultant drop in CO, which may occur abruptly. The gravid uterus may lessen venous return by compression of the inferior vena cava and less often, the aorta. Such aortocaval compression in the supine position is referred to as *supine hypotensive syndrome* and becomes more prominent as pregnancy progresses

(Toledano, 2014). Indeed, by late pregnancy, venous return from the lower extremities when a patient is supine may depend entirely on collateral circulation. General and regional anesthesia may impair sympathetic response to aortocaval compression with an inability to increase systemic vascular resistance, thus further reducing CO and hypotension. Aggressive management of maternal hypotension is critical to optimize uteroplacental perfusion during surgical procedure (Reitman and Flood, 2011). **Prevention of potential acute drops in venous return and CO may require avoidance of supine and lithotomy positions when feasible with right-side elevation to displace the uterus to the left.** Placement of a wedge may be logistically challenging, but achieving a 15- to 20-degree left tilt should reduce uterine compression of the inferior vena cava. Of note, venous compression by the expanding uterus additionally contributes to the clinical sequela of lower-extremity edema, varicosities, hemorrhoids, and critically, increased risk for deep venous thrombosis (DVT) (Antony et al., 2017; Pettker, 2017).

Respiratory

Intricate sequences of anatomic, hormonal, and metabolic alterations contribute to substantial changes in respiratory function during pregnancy. The configuration of the thoracic cage is altered during pregnancy secondary to relaxation of ligamentous attachments, with increased chest circumference by up to 7 cm (Antony et al., 2017). Diaphragmatic excursion is not impeded as gestation progresses because progesterone-mediated increases in diaphragmatic effort result in unchanged muscle function (Izci et al., 2003). Primary cranial displacement of the diaphragm up to 4 cm secondary to the expanding uterus in combination with pregnancy-related weight gain can mechanically constrict respiration. Diaphragmatic elevation, which can be up to 4 cm, decreases lung volume despite the chest wall expansion. This mechanical restriction manifests as a substantial reduction of parameters such as total lung capacity, expiratory reserve volume, and residual volume. Resultant decreases in functional residual capacity (FRC) may reach 80% of baseline values by term (Cruickshank et al., 1996). However, increased progesterone drives chronic hyperventilation, with up to a 50% increase in tidal volume by 8 weeks' gestation. This increased tidal volume drives up minute ventilation to increase alveolar oxygen and decrease alveolar carbon dioxide. Such decreased maternal serum carbon dioxide helps facilitate carbon dioxide transfer from the fetus and results in a chronic maternal respiratory acidosis. Compensation of this acidosis occurs partially from renal bicarbonate excretion.

Clinical implications for the urologist resulting from respiratory alterations in pregnancy are predominantly considerations of anesthesia and surgical positioning. Increased demand of the placenta, fetus, and maternal organs may increase oxygen consumption by up to 40% of nonpregnant levels, which lowers maternal oxygen reserves. In combination with decreased FRC, such compromise of maternal oxygen reserves creates an environment of higher susceptibility to events such as decreased oxygen saturation during intubation (Toledano, 2014). Upper airway alterations including edema of the oropharyngeal tissue, decrease in the glottic aperture, and mucosal friability complicate endotracheal tube placement and increase airway classification. Comorbidities such as obesity and preeclampsia further amplify induction issues. Supine positioning may additionally contribute to diminished FRC during general anesthesia.

Hematologic

Cardiovascular alterations in pregnancy are partially attributed to concomitant hematologic changes. Beginning at around 6 weeks' gestation, maternal blood volume progressively expands by an average of 40% to 50%. Such dramatic represents a combination of increases of both plasma volume and erythrocyte mass. However, plasma volume expansion exceeds red blood cell (RBC) mass, so maternal hematocrit decreases. Such physiologic anemia of pregnancy caused by dilutional effect reaches a nadir at 30 to 34 weeks and may be partially ameliorated by iron supplementation (Antony et al., 2017; Scott, 1972).

Additional expectations regarding hematologic issues include mild gestational thrombocytopenia (Burrows and Kelton, 1988). Platelet counts of less than 116,000 are exceedingly rare, and this threshold would mandate further evaluation, particularly in the perioperative period (Boehlen et al., 2000). However, although absolute counts decrease, there is no evidence of disruption of platelet function with intact ability to achieve hemostasis (Vincelot et al., 2001).

Indeed, for the consultant surgeon, an area of prominent importance is the state of hypercoagulability during gestation. Such hemostatic adaptation is necessary to avoid potential hemorrhage from the high-volume and low-resistance uteroplacental circulation. **Women manifest a 10-fold increased risk**

for thromboembolic disease during pregnancy as a result of a combination of venous stasis from inferior vena cava (IVC) compression and vascular trauma along with physiologic changes contributing to increases in plasma concentration of several procoagulants (Pettker, 2017). In addition to this Virchow triad of classic antecedents to venous thromboembolism (VTE), increased risk factors independent of pregnancy include age greater than 35 years, obesity, trauma, immobility, infection, smoking, nephrotic syndrome, coagulopathies, cancer, orthopedic surgery, and a history of venous thromboembolic disease. Although relatively uncommon, VTE remains a leading cause of maternal mortality and contributed to 9% of pregnancy-related deaths (Creanga et al., 2015). VTE includes DVT, primarily of the lower extremities, and pulmonary embolism, which predominantly arises from DVT.

Of concern for the consulting urologist is the independent risk for hospitalization associated with VTE, which was seventeen-fold higher than in a nonhospitalized cohort (Abdul Sultan et al., 2013). Surgical interventions during this high-risk period increase the potential complications of arrhythmia, hypoxia, pulmonary hypertension, and heart failure. Although most data in this population is regarding thromboprophylaxis for cesarean delivery, data may be extrapolated to pertain to urologic interventions. Periprocedural options to decrease VTE risk include nonpharmacologic interventions including graduated compression stockings and pneumatic compression, both of which have exceptionally favorable risk-benefit ratios (Zaccoletti and Zardini, 1992). In select high-risk circumstances with collaborative involvement of obstetrics and anesthesiology, low-dose unfractionated heparin may be appropriate therapy. Use of such therapeutic anticoagulation is contraindicated with most regional anesthesia, although unfractionated heparin may be reversed with administration of intravenous protamine sulfate. Additionally, when feasible, the left lateral decubitus position may reduce IVC compression and reduce the risk for postoperative DVT.

Of exceptional note for the urologist managing issues during pregnancy is the progressive rise in peripheral white blood cell (WBC) count during gestation. During the second and third trimesters, the mean WBC count is 8500/mm^3 (range 5600 to 12,200/mm^3) (Pitkin and Witte, 1979). This leukocytosis peaks during labor at levels up to 30,000/mm^3, complicating the use of WBC count during this period to assess for presence of infection.

Renal and Urinary Tracts

Remarkable demands on maternal resources facilitate adaptation of renal physiology during pregnancy, primarily secondary to hormonal coordination of volume expansion and vasodilation. Glomerular filtration rate (GFR) increases by 40% to 65% secondary to increased renal blood flow (Dunlop, 1981). **Increased GFR results in a decrease in serum levels of creatinine, urea, and uric acid. Of note, when determining the presence of potential renal impairment, average serum creatine during pregnancy decreases to 0.8 mg/dL** (Antony et al., 2017). Accompanying the decreased serum creatinine is a decrease in blood urea nitrogen (BUN) from an average of 13 mg/dL in nonpregnant women to 8 to 10 mg/dL during pregnancy. Renal tubular solute reabsorption compensates for renal losses because of increased GFR, balancing serum sodium. However, the threshold for stimulation of antidiuretic hormone release and thirst is decreased, resulting in a mild hyponatremia with serum sodium falling to 4 to 5 mmol/L below baseline.

Certainly, one of the most relevant parameters of interest to the urologist managing the pregnant patient is the physiologic alteration of renal function and structural changes to the upper and lower urinary tracts that occur. In addition to the metabolic changes, anatomic alterations are critical for understanding such that the urologist may discern typical findings from pathology.

Expectations during pregnancy include enlargement of the kidneys up to 1 cm. Increased size and weight is partially accounted for by dilation of the entire collecting system. **Historically on average, by term pelvicalyceal dilation is 15 mm on the right and 5 mm on the left and may be present in up to 90% of pregnancies** (Fried et al., 1983). More contemporary analysis encompassing 509 patients designed to provide sonographic reference data reported only rare dilations of the renal pelvis greater than 10 mm (Wadasinghe et al., 2016). Such dilation may begin very early in pregnancy, indicating that factors outside of mechanical compression play a role. Smooth muscle relaxation caused by higher circulating concentrations of progesterone, relaxin, and endothelin may contribute to dilation and increases in urinary dead space (Danielson et al., 1999; Gilson et al., 1992; Rasmussen and Nielsen, 1988). In fact, dilation may occur in patients with ectopic renal moieties, such as renal transplant in the pelvis. **Although smooth muscle relaxation may be a factor, mechanical compression by the gravid uterus exerts direct compression of the ureters, most predominantly on the right.** Such dilation begins by the second month and peaks during the second trimester, with ureteral diameter increasing by up to 2 cm. Discerning pathologic obstruction becomes increasingly complex, especially when combined with considerations for selective use of imaging studies to determine etiology (see Physiologic Hydronephrosis of Pregnancy later in this chapter). The clinical consequences of such collecting system distention may include increased incidence of pyelonephritis in patients with preexisting bacteriuria (see Management of Urinary Tract Infections in Pregnancy later in this chapter). Aside from rare cases with concomitant intra-abdominal pathology, expectations in the postpartum period are for complete resolution of hydroureteronephrosis.

Urine Chemistries During Pregnancy

Marked changes in renal tubular function during pregnancy result in a variety of alterations in urine chemistries that the urologist may encounter. Indeed, glycosuria during pregnancy is exceedingly common, with a 10- to 100-fold increase in urinary glucose excretion described (Antony et al., 2017). However, despite this well-documented glycosuria, the normal pattern during pregnancy is intermittent, and patients with repetitive findings should be screened by their obstetrician for diabetes.

Proteinuria and albuminuria additionally manifest during pregnancy and may increase as gestation advances. Secondary to hyperfiltration and potential reduction in tubular resorption, proteinuria during pregnancy is set at limits that exceed those of typical definitions in nonpregnant patients. In 24-hour collections, upper limits of 300 mg of proteinuria and 30 mg of albuminuria are expected, and increase from baseline occurs most dramatically in the first and second trimesters (Klein et al., 2014). Most urologists will encounter proteinuria on dipstick assessment, which is notoriously inaccurate in that renal concentration of urine is not accounted for with this method (Conrad et al., 2014). Patients with persistent proteinuria may benefit from further evaluation to rule out diabetes, preeclampsia, underlying renal disease, or urinary tract infection (UTI).

Due to fetal calcium requirements, maternal total calcium levels decline during pregnancy as reduced serum albumin results in fall of the albumin-bound fraction (Kovacs and Kronenberg, 1997). Consequently, calcinuria doubles during pregnancy. However, a physiologic parameter of importance, serum ionized calcium levels, are unchanged in the mother throughout the pregnancy.

Implications of this calcinuria on the development of urolithiasis are detailed in Urolithiasis in Pregnancy later in this chapter.

Hematuria in the Pregnant Patient

Anatomic changes during pregnancy caused by external compression from the gravid uterus may manifest in the bladder with an elevation of the trigone and increased vascularity. **Thus, microscopic hematuria is common with up to 20% of gravidas demonstrating idiopathic hematuria on dipstick urinalysis** (Antony et al., 2017; Stehman-Breen et al., 2002). Although benign in most instances, the presence of microscopic hematuria may suggest underlying pathology of exceptional impact. The most common etiologies for hematuria in pregnant patients include infection, urolithiasis, underlying renal disease, medications, trauma, obstruction, and tumors. Pregnancy-exclusive causes for hematuria include preeclampsia and placenta percreta. Further detail regarding placental abnormalities, infection, and malignancy are contained in subsequent sections of this chapter.

With regard to preeclampsia, microscopic hematuria may be found at a level of 2 to 8 times normal in these women. Preeclampsia is a systemic syndrome of pregnancy characterized by new-onset hypertension and proteinuria after 20 weeks' gestation (Maynard et al., 2016). Preeclampsia represents a critical diagnosis secondary to the risk for maternal mortality and compromised fetal outcomes. Determination of the correlation between early maternal microscopic hematuria and major adverse outcomes of pregnancy has been challenging to correlate, although most literature supports an association between idiopathic hematuria and the development of preeclampsia (Stehman-Breen et al., 2000; Stehman-Breen et al., 2002). In contradictory data, analysis of 700 pregnant women determined that 12.86% demonstrated asymptomatic idiopathic microscopic hematuria during early pregnancy, and of this population, no significant difference was revealed regarding incident pregnancy complications (Shahraki et al., 2016). A similar lack of correlation between early microscopic hematuria and preeclampsia, gestational hypertension, or small-for-gestational age infants was described in a cohort of over 900 pregnant women, thus the true implications of hematuria screening remains unclear (Brown et al., 2005).

Physiologic Hydronephrosis of Pregnancy

Critical for the consulting urologist is consideration of options for management of maternal hydronephrosis. A frequent concern from the consulting service is differentiation of physiologic versus pathologic findings, particularly in the presence of symptoms or history suspicious for anatomic obstruction. As surgeons are intimately aware, structure and function do not always correlate, and pathologic hydronephrosis is generally considered a rare entity. Of 30,552 women delivering at a single institution over a 3.5-year period, only 56 (0.2%) were admitted for symptomatic hydronephrosis (Fainaru et al., 2002). Indeed, a study of 81 gravid patients assessed longitudinally each trimester found poor correlation between symptoms of flank pain and hydronephrosis on ultrasound ($p = 0.39$) (Watson and Brost, 2006). In a prospective analysis of 51 consecutive patients at a mean gestational age of 27.5 weeks presenting with acute flank pain, maternal ultrasound and pain questionnaires discerned no correlation between the grade of hydronephrosis and pain intensity ($P = 0.466$) (Farr et al., 2017). These patients delivered at term with expected birth weights. Supporting studies stratifying 88 patients indicate that the degree of hydronephrosis does not impact ultimate outcomes of pregnancy with regard to birthweight ($P > 0.05$), although the maximal calyceal diameter was correlated to fetal weight at the time of diagnosis ($P = 0.02$) (Coban et al., 2015).

On exceptionally rare occasions, severe complications of physiologic hydronephrosis may arise, most notably the potential for calyceal rupture. First described in 1947, more than 30 case reports of this sporadic entity exist, with most of unknown etiology except for pregnancy (Boekhorst et al., 2015).

Management of symptomatic physiologic hydronephrosis in the absence of other pathologies such as calculi remains a dilemma for the urologist. A prospective randomized analysis between ureteral stenting and conservative measures demonstrated superiority for stenting with regard to symptomatic relief for moderate to severe hydronephrosis, which was offset by stent discomfort issues (Tsai et al., 2007). However, only 20% of the randomized patients were crossed over to the stent arm, implying that in most cases, conservative treatment should be favored. Conservative measures outlined in this study included analgesia, position, and intravenous fluids, and failure included signs of evolving infection or deteriorating renal function.

Supportive data for conservative therapies emerges from a case-controlled study of 53 women with symptomatic gestational hydronephrosis who were offered ureteral stenting (Cecen and Ulker, 2014). More than one-half (55%) elected conservative therapy, which again was composed of hydration, analgesia, and positioning maneuvers. Rates of complications, postpartum pain scores, or persistent hydronephrosis did not differ between groups ($P > 0.05$). The authors conclude that ureteral stent insertion in symptomatic gestational hydronephrosis does not generally add benefit over conservative treatment and should be reserved for complicated cases or additional pathologic obstructions. Analysis of 103 consecutive women with physiologic hydronephrosis revealed a 6% rate of intervention reserved for individuals manifesting overt symptoms of pyelonephritis (Puskar et al., 2001). Parameters that may increase the likelihood of surgical treatment with ureteral stenting for symptomatic hydronephrosis include maximal anterior-posterior renal pelvis diameter, parity, C-reactive protein level, WBC count, and pain on a visual analog scale (Ercil et al., 2017).

A variety of single-institution retrospective series exist supporting successful utilization of ureteral stenting for renal colic during pregnancy, although the studies are frequently contaminated by indications for obstructive pathologies such as nephrolithiasis (Choi et al., 2016; Sadan et al., 1994; Zwergel et al., 1996). Risks associated with stent insertion, in addition to known sequela of flank discomfort and irritative bladder symptoms, include rapid encrustation caused by hypercalciuria and hyperuricosuria (Goldfarb et al., 1989). However, data supporting rapid encrustation is sparse, and individualized assessment to timing of exchange is a more reasonable clinical approach. Certainly, for patients with enhanced risk resulting from the comorbidities of urinary lithiasis, frequent exchanges every 4 to 8 weeks may be optimal (Altamar and Miller, 2009).

Additional modalities of urinary drainage for refractory symptomatic hydronephrosis include percutaneous nephrostomy (PCN) drainage, which in the absence of noted obstructive pathologic condition, should be very selectively utilized because of duration of use, potential encrustation, and general discomfort with this approach.

General Considerations for Imaging of the Pregnant Patient

Important considerations for any consulting urologist, particularly with regard to management of acute situations such as urolithiasis or malignancy in pregnancy, are understanding of the recommendations for diagnostic imaging (see Chapters 3 and 4). Potential effects of irradiation on the fetus include teratogenesis, carcinogenesis, and mutagenesis. Ultimate risk depends on the gestational age and the amount of radiation delivered (Biyani and Joyce, 2002). During the first trimester, the period of early organogenesis and rapid cell division, the embryo is highly sensitive to the effects of radiation (Swartz and Reichling, 1978). Although the fetus has diminished sensitivity to the teratogenic effects of radiation in the second and third trimesters, such exposure may increase the risk for development of childhood malignant neoplasia (Harvey et al., 1985).

The American College of Obstetricians and Gynecologists (ACOG) has outlined clinical guidelines to drive management decisions and determine the diagnostic imaging modality that provides the optimal risk/benefit ratio in many situations (Committee on Obstetric Practice, 2017b). In general, each of these recommendations must be individualized to the clinical scenario, and in most cases, radiation doses for commonly employed urologic imaging are below threshold exposures with concern for fetal harm. Coordinated planning with the radiologist when feasible can often be of assistance to modify techniques to decrease total radiation dose or even acoustic output levels.

Practice recommendations from ACOG for diagnostic imaging include the following:

- Ultrasonography and magnetic resonance imaging (MRI) are not associated with risk and are the imaging techniques of choice for the pregnant patient, but they should be used prudently and only when use is expected to answer a relevant clinical question or otherwise provide medical benefit to the patient.
- **With few exceptions, radiation exposure through radiography, computed tomography (CT) scan, or nuclear medicine imaging techniques is at a dose much lower than the**

exposure associated with fetal harm. If these techniques are necessary in addition to ultrasonography or MRI or are more readily available for the diagnosis in question, they should not be withheld from a pregnant patient.

- The use of gadolinium contrast with MRI should be limited; it may be used as a contrast agent in the pregnant patient only if it significantly improves diagnostic performance and is expected to improve fetal or maternal outcomes.
- Nuclear medicine studies such as renogram to determine physiologic organ function or dysfunction may be selectively utilized during pregnancy depending on the physical and biochemical properties of the radioisotope. 99mTc (Technetium)-mercaptoacetyltriglycine (MAG3) is the most widely used renal radiopharmaceutical for urologic indications. The tracer is not filtered but is extracted by the tubules, and MAG3 renal scintigraphy is frequently employed to determine differential renal function and evaluate renal drainage parameters. In general, procedures utilizing Technetium 99m result in fetal exposure of less than 5 mGy, which is considered a safe dose in pregnancy (Committee on Obstetric Practice, 2017b). Technetium 99m has a half-life of 6 hours and is a pure gamma ray emitter, which minimizes radiation dose without image compromise, further supporting the safety of use of this agent during pregnancy.

Considerations for intraoperative fluoroscopy are always a concern for urologic surgery patients during pregnancy. Limiting radiation exposure may be accomplished by shielding of the fetus and utilizing collimation and low-dose spot films at the lowest exposure feasible for confirmation of radiographic findings during retrograde pyelogram or location for indwelling ureteral stent placement.

General Concepts for Surgical Management of the Pregnant Patient

Recommendations from the ACOG provide the urologist guidance regarding considerations for nonobstetric surgery during pregnancy (Committee on Obstetric Practice, 2017a). Overall, consultation with an obstetrician should be obtained to ensure that pertinent aspects of maternal physiology are considered along with the potential need for fetal monitoring.

Current practice recommendations from the ACOG for nonobstetric surgery include the following:

- No currently used anesthetic agents have been shown to have teratogenic effects in humans when using standard concentrations at any gestational age.
- Fetal heart rate monitoring may assist in maternal positioning and cardiorespiratory management and may influence a decision to deliver the fetus.
- **A pregnant patient should never be denied indicated surgery, regardless of trimester.**
- Elective surgery should be postponed until after delivery.
- **If possible, nonurgent surgery should be performed in the second trimester when preterm contractions and spontaneous abortion are least likely.**
- Surgery should be done at an institution with neonatal and pediatric services.
- An obstetric care provider with cesarean delivery privileges should be readily available.
- A qualified individual should be readily available to interpret the fetal heart rate patterns when applicable.

In combination with the unique physiologic challenges outlined previously that demand attention, during pregnancy there exist a variety of ethical considerations during perioperative decision-making for the urologist (Pais and

Reinstatler, 2018). Naturally there are critical diagnostic and therapeutic decisions that may directly affect not only the patient, but also the fetus. Although always a prudent maneuver to involve all stakeholders to facilitate discussion, ACOG has issued a committee opinion on maternal decision making indicating that **first and foremost, the patient's autonomy in decision making should be respected** (ACOG Committee on Ethics, 2005). Pregnant patients must be carefully counseled regarding the risks and benefits to both the patient and her child, recognizing the limitation of our medical knowledge. Overall, women should not be penalized or denied procedures just because they are pregnant.

As described previously, because of the tendency for the gravid uterus to compress the IVC, optimizing venous return often requires placing the patient in a left lateral decubitus position when feasible. This left lateral position should be modified and considered during open, laparoscopic, and endoscopic procedures.

Choice of surgical approach is predicated on surgeon experience and the exposure requirements. No randomized trials exist to compare open and laparoscopic procedures in the pregnant patient, but much available data suggest equal outcomes (Cunningham et al., 2013a). In general, laparoscopic procedures compare to laparotomy with regard to infant survival or fetal malformation, although earlier delivery and lower birth weight have been associated with laparoscopy in this setting (Reedy et al., 1997). In addition to careful consideration for port site placement under direct visualization based on fundal height, the Society of American Gastrointestinal Endoscopic Surgeons (SAGES) has created specific recommendations for laparoscopy during all trimesters of pregnancy, which may be extrapolated for a variety of urologic interventions (Pearl et al., 2011). They conclude that insufflation between 10 and 15 mm Hg may be safely employed during pregnancy. Higher insufflation pressures resulted in maternal cardiovascular and respiratory changes after 20 minutes, which should be avoided. Additionally suggested by the SAGES guidelines is utilization of intraoperative maternal end-tidal capnographic monitoring.

In most cases, excessive perinatal mortality has been attributed to the disease process itself rather than the morbidity of undergoing a surgical procedure (Mazze and Kallen, 1989). An association of preterm labor has been identified with general surgical procedures performed during the third trimester (Visser et al., 2001). Although no fetal loss was noted, preterm delivery occurred in 16% of pregnant patients requiring third-trimester interventions. Critical to the urologist for counseling, and further discussed later, is the 10% incidence of preterm labor demonstrated with ureteroscopic procedures during the third trimester (Johnson et al., 2012). This data reiterates the ACOG recommendations to perform nonurgent surgery during the second trimester, when preterm contractions and spontaneous abortion are least likely.

General Concepts of Urologic Medication Administration During Pregnancy

Prescription medication use during pregnancy is almost universal, with 97.1% in a cohort of over 9000 women reporting taking at least one medication during their pregnancy (Haas et al., 2018).

In 2015, the US Food and Drug Administration (FDA) substantially redesigned its regulations regarding the content of labeling for human prescription drugs and biologic products with regard to providing information for pregnancy (FDA, 2014). For decades, alphabetical categories were employed to convey risk based on known preclinical or clinical information. The modified rule requires removal of the pregnancy categories A, B, C, D, and X from all human prescription drug and biologic product labeling. The FDA guidance additionally requires that the labeling include a summary of the risks of using a drug during pregnancy and lactation, a discussion of the data supporting that summary, and relevant information to help health care providers make prescribing decisions and counsel women about the use of drugs during pregnancy and lactation. The promise is that the new labeling will create a consistent format for providing information about the risks and benefits of prescription drug and/or biologic product use during pregnancy. The challenge for the practitioner with infrequent need to access this information for the pregnant patient will be careful translation of the available evidence as opposed to a familiar system of general classification (Pernia and DeMaagd, 2016). Medications will require an individualized review without such previously standardized schema as the category system.

To provide the reader with the most contemporary information regarding safety of the wide variety of pharmaceuticals employed by the urologist, the practitioner is directed to the most current data available on the FDA website (FDA, 2018). Naturally, in addition to evaluation by the prescribing provider, consultation with the patient's obstetrician is prudent to ensure safety and continuity of care for both the mother and fetus. Exceptionally specific information regarding the teratogenic potential of a variety of commonly employed medications is outside the scope of this chapter but is elegantly detailed elsewhere for urologists desiring more extensive knowledge (Niebyl et al., 2017).

Of special mention are highly specific biologic agents in widespread use in urology. OnabotulinumtoxinA (BoNT-A) is one such agent in which application has revolutionized the treatment algorithms associated with idiopathic and neurogenic lower urinary tract symptoms. Dominant to this increased utilization is the relative ease of administration and low complication profile. With regard to use during pregnancy, prescribing information from the manufacturer indicates, based on animal data, BoNT-A may cause fetal harm (Allergan, 2018). In animal models, intramuscular injection resulted in reductions in fetal body weight and skeletal ossification. During the critical phases of organogenesis in rats and rabbits at doses that extrapolate to the maximum recommended human dose of 400 Units, daily injections revealed significant maternal toxicity, abortions, early deliveries, and even maternal death. However, a single dose at three different periods resulted in no adverse effect on fetal development. Overall, it is recommended to only employ BoNT-A during pregnancy if the benefit significantly outweighs the risk. Likewise, it remains unknown if BoNT-A is secreted in breast milk, so caution should be exercised when administering it to nursing mothers. Review of a global safety database of 232 pregnancies with maternal BoNT-A exposure revealed a prevalence of fetal defects comparable to rates in the general population (Brin et al., 2016). Limitations of extrapolation of the data in this report include that only 6 patients underwent injection for urologic indications.

Urolithiasis in Pregnancy

Urolithiasis remains one of the most frequent and often complex urologic consultations during pregnancy. With a reported incidence between 1 : 200 to 1 : 1500 pregnancies, renal colic secondary to kidney stones is the leading nonobstetric cause for hospitalization in the pregnant patient (Gorton and Whitfield, 1997; Riley et al., 2014; Rodriguez and Klein, 1988). Substantial morbidity to both mother and fetus are imposed by the pain of renal colic, urinary infection, and urinary tract obstruction, which associate urolithiasis with increased risk for preterm delivery, preeclampsia, placenta previa, and preterm premature rupture of membranes (Banhidy et al., 2007; Hendricks et al., 1991; Lewis et al., 2003; Maikranz et al., 1987; Rosenberg et al., 2011; Swartz et al., 2007). Despite the increased risk for pregnancy complications, no statistically significant impact on birth outcomes as measured by low birth weight, decreased Apgar scores, or perinatal mortality have been associated with symptomatic urolithiasis (Rosenberg et al., 2011).

Although there is a recognized increase in the incidence of urolithiasis in the general population over the past several decades, particularly in women, a concomitant increase in pregnant women above age-matched nonpregnant women has not been documented (Coe et al., 1978; Hendricks et al., 1991; Riley et al., 2014; Scales et al., 2007, 2012). Multiparous women have been reported to be acutely affected more often than primiparous women, in some cases by a ratio of approximately 3 : 1 (Horowitz and Schmidt, 1985; Rodriguez and Klein, 1988). However, when adjusted for age, the incidence for multiparous women is no greater than that for primiparous women (Swanson et al., 1995). Contemporary data utilizing a large, nationally representative population-based survey reveals a strong relationship between prior pregnancy and subsequent episodes of nephrolithiasis (Reinstatler et al., 2017).

Despite the predominance of right-sided hydronephrosis, there is a similar incidence of left and right symptomatic calculi (Parulkar et al., 1998; Rosenberg et al., 2011; Stothers and Lee, 1992). Most patients with symptomatic calculi present during the second or third trimester (Denstedt and Razvi, 1992; Stothers and Lee, 1992; Swanson et al., 1995).

Etiology

As extensively outlined earlier, pregnancy induces significant physiologic alterations including dramatic changes of both anatomy and physiology of the upper urinary tract (see Physiologic Changes During Pregnancy). To briefly recap, the most remarkable anatomic change is the dilation of the renal calyces, pelvis, and ureters, usually evident by 6 to 10 weeks' gestation. Physiologic hydronephrosis is the most common cause of dilation of the urinary tract in pregnancy and may produce pain that mimics renal colic from urolithiasis. Upper-tract dilation with a right-sided predominance is reported in up to 90% of pregnant women by the third trimester and may persist up to 12 weeks postpartum (Boridy et al., 1996; Schulman and Herlinger, 1975). Rarely, spontaneous rupture of the calyx may occur, again with a right-side predominance (Loughlin, 1994; MacNeily et al., 1991).

Both humoral and mechanical factors have been implicated in the cause of hydronephrosis in pregnant women. Increases of circulating progesterone during pregnancy results in relaxation of ureteral smooth muscle, potentially reducing peristalsis (Paller and Ferris, 1996). Recent evidence suggests that mechanical factors such as compression of the gravid uterus on the ureters is likely to be primary in the pathogenesis of hydronephrosis of pregnancy because of right predominance and rare dilation below the pelvic brim (Rasmussen and Nielsen, 1988; Schulman and Herlinger, 1975). Mixed data exist regarding women with altered urinary anatomy and hydronephrosis, but in general mechanical compression as a mechanism predominates (Dafnis and Sabatini, 1992; Rasmussen and Nielsen, 1988; Swanson et al., 1995).

When considering urolithiasis, other important physiologic changes in pregnancy outlined earlier (see Physiologic Changes During Pregnancy) include a 30% to 50% increase in GFR, modifying the interpretation of serum creatinine and BUN (Paller and Ferris, 1996). Critical for consideration with urolithiasis, **elevation in renal plasma flow and GFR also increases the filtered loads of sodium, calcium, and uric acid, resulting in a state of hypercalciuria and hyperuricosuria** (Boyle et al., 1966; Gertner et al., 1986; Howarth et al., 1977). Hypercalciuria is further exacerbated by the suppression of parathyroid hormone and the increase in circulating 1,25-dihydroxycholecalciferol production by the placenta, increasing intestinal absorption of calcium. Twenty-four–hour urine chemistries in pregnant patients demonstrated that urinary pH is elevated during pregnancy, most dramatically during the second trimester (Resim et al., 2006). However, these potentially lithogenic physiologic changes are offset by an increase in the excretion of urinary inhibitors, such as citrate and magnesium, as well as an increase in urine output (Biyani and Joyce, 2002). It has been postulated that metabolic alterations in the urine may contribute to the accelerated encrustation of ureteral stents during pregnancy (Denstedt and Razvi, 1992; Loughlin, 1994). Stones that occur during pregnancy are most commonly calcium phosphate in composition, a finding that may be explained by the relatively elevated urinary pH and hypercalciuria that occur in the pregnant state (Ross et al., 2008).

Evaluation

Although renal colic is the most common nonobstetric cause of abdominal pain in hospitalized pregnant patients, the diagnosis of urolithiasis in the pregnant patient remains challenging as many of the usual manifesting signs and symptoms may be masked by the patient's gravid status. As gestation progresses, the perception and localization of pain may be altered, and it has been reported that 28% of pregnant patients ultimately diagnosed with an obstructing stone were initially incorrectly diagnosed with appendicitis, diverticulitis, or placental abruption (Stothers and Lee, 1992). **The most common presenting symptom in pregnant patients remains flank pain, usually accompanied by either macroscopic or microscopic hematuria and, in some cases, UTI.** As outlined earlier, hematuria without discomfort is unusual in patients with obstructing stone disease (Swanson et al., 1995). Of importance in the pregnant patient is obtaining a urine culture as pyuria may be present at baseline, which diminishes the sensitivity of this parameter for detecting UTI (Hendricks et al., 1991; Houshiar and Ercole, 1996; Parulkar et al., 1998). A diagnosis of urinary calculi should be considered in evaluation of a pregnant patient who suffers from persistent infection with a urea-splitting organism. Vigilance in evaluation is mandated as many of the other nonspecific symptoms of urolithiasis including irritative voiding symptoms, chills, nausea, and emesis may occur with other intra-abdominal conditions.

The American Urological Association (AUA) has developed guidelines for surgical management of stones that specifically evaluate and address issues with management of the pregnant patient (Assimos et al., 2016a, 2016b). The panel acknowledges the challenges of diagnosis and treatment of stone disease during pregnancy because of the undue risks imposed to the developing fetus and inaccurate clinical presentation. **A multidisciplinary approach is strongly recommended with involvement of the obstetrician or maternal-fetal**

medicine physician, anesthesiologist, pharmacist, and urologist in collaboration to develop a safe and effective plan for the patient.

Imaging studies are the mainstay of diagnostics for urolithiasis in the pregnant patient when presenting symptoms and physical examination may be insufficient. Critical to determination of the optimal strategy for imaging, as discussed earlier (see General Considerations for Imaging of the Pregnant Patient), the ACOG has issued guidelines that may apply to urolithiasis designed to optimize safety for the developing fetus (Committee on Obstetric Practice, 2017b).

Practice recommendations from the ACOG for diagnostic imaging include primary use of ultrasonography and MRI as they are not associated with fetal risk, but still they should be used prudently and only when use is expected to answer a relevant clinical question or otherwise provide medical benefit to the patient. Indeed, ultrasonography has become the standard initial study in evaluation of the pregnant patient with suspected renal colic. Unfortunately, ultrasound is operator-dependent, and it can be exceptionally difficult to adequately visualize the ureter or distinguish physiologic hydronephrosis of pregnancy from ureteral obstruction because of calculus. In the pregnant patient, renal ultrasonography for the detection of calculi had a reported sensitivity of only 34% with a specificity of 86% (Stothers and Lee, 1992). Similar data suggest ultrasonography resulted in definitive diagnosis in only 60% of pregnant patients (Butler et al., 2000).

Several techniques have been suggested to improve the diagnostic capability of ultrasonography. Color Doppler imaging has been proposed to elucidate ureteral jets as this is a highly sensitive tool for obstruction (Deyoe et al., 1995). However, in the pregnant patient, ureteral jets may be unpredictable, and use of this technique for assessment of obstruction should be employed with caution (Burke and Washowich, 1998; Masselli et al., 2013).

Doppler ultrasound can additionally be utilized to calculate renal vascular resistance, which increases in the presence of acute obstruction (Ulrich et al., 1995). In a prospective analysis of 117 nonpregnant patients with ultrasonography, resistive index (RI) measurements had a 77% sensitivity and an 83% specificity in diagnosis of ureteral calculi, and a change in RI had an 88% sensitivity and a 98% specificity (Shokeir and Abdulmaaboud, 1999). Critical to understanding is that renal RI remains unchanged from the nonpregnant state throughout the course of pregnancy and is also unaffected by the physiologic hydronephrosis of pregnancy, which suggests that this imaging modality may be useful in detecting acute obstruction in this population (Horrigan et al., 1996). Operational use of RI in pregnant women found it had a 45% sensitivity and a 91% specificity in detecting an obstructing ureteral calculus, and a change in RI had a 95% sensitivity and a 100% specificity (Shokeir et al., 2000). Transvaginal ultrasound may also be utilized to provide imaging of the distal ureter. Overall, studies indicate that 14% of women undergoing intervention for a radiographically detected stone ultimately were found to harbor no such stone (White et al., 2013).

An additional recommended imaging modality in the pregnant patient is MRI. MRI does not rely on ionizing radiation or contrast medium, making it a potentially attractive tool for pregnant patients, however there are significant limitations for evaluation of urolithiasis. Because MRI does not visualize calcium, stones are visualized as filling defects overlying the high signal intensity of urine. Elucidation of smaller stones with this technique is difficult (Hattery and King, 1995; Roy et al., 1995). In symptomatic patients, MRI has been reported to accurately differentiate physiologic hydronephrosis of pregnancy from hydronephrosis resulting from an obstructing ureteral calculus (Spencer et al., 2004). Other techniques described include a half-Fourier acquisition single-shot turbo spin-echo (HASTE) MRI protocol to increase the utility of MRI in the evaluation of pregnant patients (Mullins et al., 2012).

Other imaging techniques for evaluation of urolithiasis in pregnancy including intravenous pyelogram and nuclear renography are fraught with limitations and should be infrequently employed in contemporary urologic practice (Biyani and Joyce, 2002; Stothers and Lee, 1992).

In the nonpregnant patient, noncontrast CT remains the gold standard for diagnosis of urolithiasis with almost 99% sensitivity and specificity. CT has been historically avoided in pregnancy because of the previously outlined risks of ionizing radiation to the fetus. However, as reported by ACOG, with few exceptions, radiation exposure via CT scan is at a dose much lower than the exposure associated with fetal harm. If these techniques are necessary in addition to ultrasonography or MRI or are more readily available for the diagnosis in question, they should not be withheld from the pregnant patient.

Utilization of low-dose radiation exposure CT has emerged as a technique of high utility and low risk for the pregnant patient and fetus (White et al., 2007). Although generally not employed as first-line diagnostics, low-dose CT in pregnancy reports a positive predictive value of 95% for urolithiasis and is additionally useful for potential nonurologic pathologies (White et al., 2013).

Protocols for ultra–low-dose CT may provide even greater utility for the pregnant population (Rob et al., 2017). Current **AUA guidelines suggest if ionizing radiation is necessary for diagnostic or treatment purposes, the radiologist along with the obstetrician can estimate radiation exposure so the total pregnancy exposure does not exceed the ACOG recommended maximum of 50 mGy.**

Following carefully metered use of diagnostic imaging, many considerations regarding optimal management must be devised for the pregnant patient. According to AUA guidelines, spontaneous passage rates for pregnant patients with ureteral stones have not been demonstrated to be different than those of nonpregnant patients. Therefore, in a patient whose symptoms are controlled, a period of observation should be the initial therapy. **Of pregnant patients with symptomatic calculi, 50% to 80% will pass their stones spontaneously when treated conservatively with hydration and analgesia** (Denstedt and Razvi, 1992; Gorton and Whitfield, 1997; Parulkar et al., 1998; Stothers and Lee, 1992). However, a stone event in pregnancy carries with it an increased risk for maternal and fetal morbidity, so patients should be followed closely for recurrent or persistent symptoms (Rosenberg et al., 2011; Swartz et al., 2007).

Pain management in the pregnant population is an actively evolving field with the traditional analgesic routine being frequent, small-dose administration of morphine (Valovska and Pais, 2018). Note that nonsteroidal anti-inflammatory agents such as ketorolac are contraindicated in pregnancy secondary to risk for fetal pulmonary hypertension and premature closure of the ductus arteriosus if administered in the third trimester.

In general, coordination with obstetrics should be performed to individualize pain management strategies for the patient's clinical situation and fetal risk. In the nonpregnant population, medical expulsive therapy (MET) with alpha-blockers or calcium channel blockers is frequently considered to facilitate stone passage by promoting relaxation of ureteric smooth muscle (McClinton et al., 2014). AUA guidelines for the nonpregnant patient endorse the use of MET for uncomplicated small distal stones with alpha-blockers (Assimos et al., 2016a, 2016b). The panel additionally reports that should MET be considered for the pregnant patient, the patient should be counseled that MET has not been adequately investigated in the pregnant population, and the pharmacologic agents are being used for an “off-label” purpose (Bailey et al., 2016).

Should a trial of observation fail, pregnant patients should be offered interventions. Intervention is required in approximately one-third of patients, usually for pain uncontrolled by analgesia or signs of persistent obstruction and infection. Generally, management options include temporizing measures such as ureteral stent placement or PCN drainage and definitive management via a variety of techniques. Overall, if surgical intervention is warranted, creation of a multidisciplinary team as described earlier (see General Concepts for Surgical Management of the Pregnant Patient) is imperative to optimize outcomes and limit risks.

When treatment is selected, it should be recognized that there remains controversy regarding the most appropriate method of intervention. Some authors have maintained that ureteral stents are the optimal treatment for such patients. Although ureteral stents effectively drain an obstructed collecting system, they are by no means the perfect solution to this problem. The changes in urinary chemistry that occur during pregnancy, hypercalciuria and hyperuricosuria, have been implicated in the accelerated encrustation of ureteral stents. Because of this phenomenon, multiple studies have recommended ureteral stent exchange in pregnant patients every 4 to 6 weeks (Valovska and Pais, 2018). For a woman in an early gestational stage, this fates her to multiple stent changes over the course of the pregnancy. An indwelling stent places these patients at an increased risk for bacteriuria, UTI, and stent migration, all of which are serious morbidities that may have an adverse effect on the pregnancy. Ureteral stents themselves are associated with pain, which can have a negative effect on a patient's quality of life.

Percutaneous nephrostomy drains are an alternative treatment option for pregnant patients with obstructing renal calculi. Just as with ureteral stents, nephrostomy tubes will effectively drain an obstructed collecting system. However, many of the same limitations that apply to ureteral stents also apply to nephrostomy drains including encrustation, colonization, pain, dislodgement, and the need for multiple interventions. In an analysis of 29 pregnant women managed with nephrostomy drainage, over one-half required tube exchanges, replacements, or flushing because of either dislodgement or obstruction (Khoo et al., 2004). Indeed, the majority of pregnant patients managed with nephrostomy drainage required exchange of the tube because of occlusion from debris (Kavoussi et al., 1992). One-third of the patients in this series ultimately required nephrostomy removal because of recurrent drain obstruction, fever, or pain.

Ultimately with either temporizing ureteral stent placement or nephrostomy drain placement, in most instances the patient will require a definitive procedure in the postpartum period for stone removal. As such, a trend toward offering definitive therapy with ureteroscopy (URS) in pregnant patients in the second trimester has recently evolved. Overall, complications in pregnant patients undergoing URS are uncommon. **Systematic review of over 100 pregnant patients who underwent URS reported an overall complication rate of 8.3%, with no significant difference in rates of urinary tract complications compared with the nonpregnant population** (Semins et al., 2009). With regard to obstetric outcomes, a multicenter trial that examined URS in pregnant women reported a complication rate of 4% (Johnson et al., 2012).

Critical to performing URS is consideration for fetal ionizing radiation exposure intraoperatively resulting from use of fluoroscopy. **Strategies to reduce or eliminate radiation exposure include use of low-dose or pulsed fluoroscopy with collimation to minimize scatter combined with lead shielding of the pelvis placed below the patient, direct visualization without fluoroscopy, or employment of intraoperative ultrasound guidance** (Deters et al., 2013).

Other treatment modalities frequently effective in the nonpregnant patient are not appropriate for this population. Although there have been reports of the inadvertent treatment of pregnant patients with shock wave lithotripsy, with no adverse sequelae to the fetus, pregnancy remains a contraindication to this treatment modality (Chaussy and Fuchs, 1989; Frankenschmidt and Sommerkamp, 1998). Likewise, highly invasive therapies such as percutaneous nephrolithotomy should be deferred until after delivery because this procedure often requires prolonged anesthesia and radiation exposure.

Key Points

- Ultrasonography is the standard initial imaging study in evaluation of the pregnant patient.
- A trend toward offering definitive therapy with URS in pregnant patients in the second trimester has evolved with acceptable complication rates.
- **It is important to minimize ionizing radiation exposure to the pregnant patient during URS by use of a below-table x-ray source and to shield the fetus with a lead apron placed below the patient.**

Pregnancy in Women With Congenital Urologic Conditions

Myelomeningocele

Individuals with myelomeningocele (MMC) present unique challenges for the urologist at baseline that escalate with the addition of pregnancy. Considerations include patient age, underlying comorbid disease, genetic implications for the offspring, pelvic bony and muscular anatomy, obesity, urinary diversion status, prior abdominal surgery, renal function, and presentation of the fetus. Appreciation of these physiologic, anatomic, and social considerations should guide the physician to optimize organization of multidisciplinary care for these patients.

Fertility

In general, female patients with MMC are considered to have normal fertility, with up to 70% of those who conceive having successful pregnancies (Jackson and Mott, 2007). However, as discussed in detail later in this chapter, the gravid uterus may impact already tenuous balance and ambulation issues, ventriculoperitoneal (VP) shunt drainage, bowel and bladder function, urinary diversion function, skin integrity, pulmonary function, cardiac function, and foremost, urinary infection risk. For patients who have previously undergone extensive pelvic surgery, experienced authors have suggested that visceral adhesions may negatively affect fertility because of uterine retroflexion and concomitant issues with conception and implantation (Hautmann and Volkmer, 2007; Thomas and Adams, 2009).

Urologists are intimately familiar with the risks of latex allergies in the congenitalism population, estimated to affect up to 60% of patients (Ricci et al., 1999; Sparta et al., 2004). Although most surgeons are accustomed with and prepared for the intraoperative consequences of a latex allergic reaction, special considerations may necessary when counseling patients regarding sexuality and birth control. Primarily, patients must be cognizant to utilize latex-free condoms, sexual aids, and intrauterine devices.

Preconception counseling is strongly encouraged when the opportunity exists and the pregnancy is planned. Involvement of a multidisciplinary team with high-risk obstetrics, urology, anesthesiology, orthopedics, and neurosurgery should be considered for consensus decision-making for the MMC patient desiring pregnancy. Provision for social work counseling may furthermore be exceptionally valuable. Genetic components of neural tube defects must be clearly delineated for MMC patients desiring conception. Risk for transmission to offspring if one parent is afflicted with MMC is variably quoted at 1% to 8% (Cameron and Moran, 2009; Laurence and Beresford, 1975; Mitchell et al., 2004). The threat is identical if the affected parent is male or female; however, the incidence in female offspring is 1 in 13 and diminishes to 1 in 50 for male children. However, if both parents are affected, the neural tube defect transmission rate increases dramatically to 15%.

Pregnancy

Pregnancies for MMC patients most often follow urinary tract surgery by many years with the initial goals of reconstruction likely aimed at protection of renal function and social continence with few considerations for eventual pregnancy. Although each patient presents a unique challenge, some concepts may be broadly applied for the MMC patient. Foremost is recognition that **the greatest risk factor for worsening renal function in pregnant patients with or without urinary reconstruction is preexisting renal insufficiency** (Thomas and Adams, 2009). Significant pregnancy-related loss of maternal renal function along with development of new-onset hypertension has been demonstrated, increasing the complication rates of preterm delivery and growth restriction (Chu et al., 1996; Hou, 1985). Superimposed on the issues of renal function is the recognition that some MMC patients may have a solitary kidney because of congenital absence or loss from dysfunction (Hautmann and Volkmer, 2007). It is critical to initiate assessment with a measurement of GFR as opposed to a singular creatinine value to accommodate for the altered body habitus and muscle mass when making decisions regarding treatment.

Combined with the increased risk for development of urolithiasis demonstrated for patients with urinary diversion, the complexities of the physiologic and anatomic changes that accompany pregnancy may be amplified in the congenitalism population. Risk for both upper and lower urinary tract calculi in patients with bladder augmentation have been variably estimated from 9% to as high as 50% (Welk and Herschorn, 2012). Although some hazard may be attributed to anatomic parameters such as incomplete emptying of continent reservoirs, contributing factors include chronic bacteriuria, intravesical foreign bodies, mucus secretion, metabolic acidosis, enteric hyperoxaluria, and dietary culprits (Hamid et al., 2008; Robertson and Woodhouse, 2006). Physiologic and anatomic changes of pregnancy may exacerbate the complexities of the MMC predisposition for calculi. Notably, extrinsic obstruction of the ureter by the gravid uterus against the pelvic brim may worsen preexisting hydronephrosis and urinary stasis, potentially predisposing to impairment of renal function or promotion of urinary infection. **Hydronephrosis of pregnancy after lower urinary tract reconstruction tends to worsen during weeks 20 to 28 of gestation, requiring increased vigilance of monitoring during this period** (Greenwell et al., 2003).

Fortunately, as addressed in the previous section, because of the protective effects of increased secretion of several inhibitors of urinary stone formation such as citrate, magnesium, and glycosoaminoglycans, even patients with a known history of stone disease do not experience an increased rate of urolithiasis during pregnancy (Altamar and Miller, 2009). However, in the MMC patient with altered body habitus and potential urinary diversion status, high levels of vigilance are mandated to detect manifestation of clinically significant stones during pregnancy. Of concern in this population is the altered sensory capacity to recognize upper tract obstruction, which may delay care until devastating systemic symptoms are present.

There is little guidance with regard to the retained bladder for patients with diversion without concomitant cystectomy. Some authors suggest that concerns involving a retained nonfunctional bladder, such as pyocystis, may unfortunately only become overt during pregnancy (Hautmann and Volkmer, 2007).

In addition to hydronephrosis, notable matters that may occur during the MMC pregnancy include **compromise of vascular perfusion of the diversion bowel segment, intestinal obstruction, stenosis or prolapse of a urostomy, compression of catheterizable channels, and metabolic complications** (Hautmann and Volkmer, 2007). Of special concern in patients with ureterosigmoidostomy is the possibility of mechanical deformation of the sigmoid or ureteral anatomoses, potentially resulting in disruption of the ureteral implants or incomplete emptying. Notably, rectal sphincter function necessary for appropriate function of the ureterosigmoidostomy may be compromised by vaginal delivery, leading to de novo urinary and potentially fecal incontinence. See later in this chapter for a discussion of the complexities of urinary diversion during pregnancy.

Mode of Delivery

Mode of delivery of the infant remains a controversial topic with a myriad of considerations. Before accurate counseling and planning for delivery, priority must be given to obtaining comprehensive records on prior surgical interventions and urinary tract evaluations including urodynamics and upper-tract studies. Although often the complete operative record will rarely be available for review, obtaining as much primary source information regarding specific procedures cannot be underscored. Individual practice patterns for pediatric reconstruction, in addition to often multiple operative revisions, make understanding the patient's anatomy a top priority.

Factors influencing the choice of delivery mode beyond the standard obstetric concerns include the type of diversion or prior surgical interventions, anatomic issues related to the underlying disease process, and fetal presentation (Hautmann and Volkmer, 2007). Continence may be impacted during the post–vaginal delivery period for patients with native urethras or ureterosigmoidostomy; this information should influence patient counseling. Vaginal delivery is not contraindicated in patients with augmentation cystoplasty in the setting of a native bladder neck and urethral continence mechanism. However, **for individuals with bladder neck reconstruction, vaginal delivery potentially carries a risk for injury to the pelvic support and continence mechanisms.** Although no consensus regarding expectations in this setting exist, data from a widely circulated survey regarding delivery mode for MMC with bladder neck reconstruction or artificial urinary sphincter indicated most practitioners would recommend cesarean section for these individuals (Hill et al., 1990). Few reports of pregnancy in the setting of an AUS exist, but available data suggest that a functioning AUS does not impact the complication profile during pregnancy and delivery (Fishman and Scott, 1993). Caveats are readily noted in these studies, such as the avoidance of high forceps delivery, and clearly no consensus of recommendation exists as most of these observations are anecdotal because few women face these dilemmas.

Previous incontinence procedures, most notably the prior placement of a pubovaginal sling, may also drive decisions regarding type of delivery. Some series have suggested that prior bladder neck sling does not preclude vaginal delivery because of the risk for incontinence (Tan et al., 2010). Literature reviews of the small patient numbers reported with pregnancy after synthetic mid-urethral sling suggest only a moderate decrease in continence after either vaginal or cesarean delivery (Huser et al., 2012). Overall urinary continence rates of 91.7% were noted during pregnancy and 80.6% during the postpartum. The majority of women in these studies (58.3%) proceeded with vaginal delivery. Certainly, for patients with any prior incontinence procedure, risks for functional injury and loss of continence with vaginal delivery should be discussed as they approach 19% in the overall population (Pollard et al., 2012). Although impossible to generalize this data to the MMC population because of the variation in risk factors, clearly some threat of continence disruption exists.

Discussion of long-term risk to continence and recommendation for the mode of delivery must be individualized. If vaginal delivery is primarily chosen, careful consideration must be given to avoidance of prolonged labor to reduce pelvic floor trauma. If cesarean section is chosen, emergent or elective, it is critical to involve a urologist familiar with the anatomy to reduce incidence of injury to the bladder or vascular pedicle. Patient proximity to appropriate levels of high-risk obstetric care may additionally drive decisions once labor has initiated as such patients may elect cesarean section in lieu of prolonged labor at a primary facility with the potential need for emergent cesarean section without appropriate adjunct expertise.

Patients with MMC frequently display elements of pelvic organ prolapse (POP) at baseline, which may be exacerbated by pregnancy and both vaginal delivery and even cesarean section. If the prolapse is significant enough to warrant operative repair before pregnancy, it may be prudent to avoid vaginal delivery as worsening of the prolapse may be inevitable in that setting. Another prominent anatomic consideration includes bony and muscular anatomy and capacity to abduct the hips, which may in some instance preclude the capacity for vaginal delivery.

An additional challenge with vaginal delivery that may depend on the level of the spinal dysraphism is difficulty generating sufficient Valsalva effort required to progress through the later stages of labor (Natarajan et al., 2002). Of course, the gravid uterus may exacerbate background restrictive airway disease by compressing the diaphragm and resulting in a potential for respiratory compromise.

As elegantly outlined by Hautmann and Volkmer (2007), pragmatic concerns that dictate options for mode of delivery are outlined as follows:

Vaginal delivery should be considered contraindicated in the following MMC patients:

- Patients with a narrow bony pelvis

- Patients with artificial sphincters or bladder neck reconstructions
- Patients with contracted hips

Vaginal delivery should be performed with caution in the following patients:

- Patients with ureterosigmoidostomy
- Fetal malpresentation
- Patients with uterine prolapse

Likewise, the authors endorse the following concerns should be noted for patients regarding proceeding with cesarean section:

- Patients with intraperitoneal VP shunts
- Patients with diversion pouches, enterocystoplasty, or neobladder

Technical considerations with cesarean section include performing the procedure via a high midline incision to avoid damage to the reservoir (Hensle et al., 2004; Hill et al., 1990). Catheterization of channels in the immediate preoperative period may assist with either avoidance or recognition of injury induced by the dissection.

An item of concern when contemplating pregnancy and cesarean section in the MMC population is the presence of a VP shunt. VP shunts are common in the patient with MMC, and hydrocephalus and malfunction during pregnancy may be associated with headache, nausea and emesis, and even potentially impaired consciousness (Hautmann and Volkmer, 2007). Functional obstruction caused by the gravid uterus increasing intra-abdominal pressure or mechanical obstruction may additionally cause neurologic sequela (Cusimano et al., 1990; Wisoff et al., 1991). Of significant concern is the potential for shunt infection during intra-abdominal surgery, particularly emergent cesarean section. This infection risk may be increased in the presence of prior urinary tract reconstruction with the possibility of spillage of contaminated urine into the peritoneal cavity containing the VP shunt.

Also dependent on the specific lesion level in MMC patients is the capability to detect the onset of labor (Daw, 1973). Curiously, although paraplegia does not appear to affect the contractile properties of the uterus, as mentioned earlier, the final stages of labor may be compromised because of deficits in the coordinated muscular effort necessary for the final stages of labor (Robertson, 1972; Stanton, 1974).

Prevention of Neural Tube Defects

Because polymorphisms in the folic acid metabolism pathway are considered primary deficits in the development of neural tube defects, promotion of folic acid supplementation for women desiring pregnancy is of critical importance (Wilson et al., 2003). By the early 1990s, a substantial public health effort was initiated in the United States through the collaboration of the Centers for Disease Control and Prevention, Health Services Administration, FDA, and the National Institutes of Health (1993). This program involved a three-stage approach for the prevention of neural tube defects: (1) dietary supplementation of 0.4 mg of folic acid for low-risk women and 4 mg of folic acid for high-risk women of childbearing age; (2) improvements in dietary habits; and (3) fortification of the US food supply. Notably, compared with routine supplementation of women without MMC of 0.4 mg folic acid per day, **doses of 4 to 5 mg per day have been advocated for the MMC patient desirous of fertility** (de Vylder et al., 2004). Prophylaxis is currently recommended with folic acid supplementation for 3 months before pregnancy and continuing through week 12 after delivery. Despite this regimen, there remains a risk for development of MMC caused by inborn errors of metabolism or discrepancies in the absorption of folic acid products (Leung et al., 2013). Additional genetic, dietary, and epigenetic alterations responsible for these continued hazards for development of neural tube defects are topics of vigorous current research initiatives in the postfolate supplementation era.

Monitoring and counseling of progeny for neural tube defects should be employed and tailored to the individual desires of the parents (Trudell and Odibo, 2014). Prenatal diagnosis of neural tube defects has been incorporated into routine prenatal care via screening through maternal serum alpha-fetal protein combined with ultrasound. Fetal MRI may also serve as an adjunct imaging modality with ultrasound to improve prognostic prediction.

Classic Bladder Exstrophy

Bladder exstrophy (BE) is an exceptionally complex and rare anomaly occurring in approximately 1 in 30,000 live births, with a generally accepted male predominance (Ebert et al., 2009). Treatment of the urologic and gynecologic consequences of classic BE in female children is an exceedingly intricate endeavor. Remarkable technical progress in the past several decades, spearheaded by comprehensive urologic care protecting renal function, has resulted in many BE patients once destined for death surviving to adulthood. Yet very few mechanisms exist to ensure a continuity of care for this unique population, particularly with regard to pelvic floor disorders, sexual function, fertility, and pregnancy (Eswara et al., 2016).

Genital Anatomy

Classic BE is a congenital malformation presenting with a spectrum of anatomic challenges arguably unparalleled in urology. Female BE patients display varying degrees of characteristic pubic diastasis accompanied by anterior displacement of the labia majora, vagina, and anus; a bifid clitoris; and a notable protrusion of the bladder through the abdominal wall defect (Gearhart and Mathews, 2016). The collection of insults to the female pelvic floor predisposes to a myriad of conditions as the BE patient ages (Miles-Thomas et al., 2006). Overall, the combination of bony pelvis and pelvic floor muscular defects contribute to severe compromise of the levator ani anterior support of the genitourinary and gynecologic pelvic organs (Stec, 2011). In general, women with BE display a reduction in vaginal depth with retained caliber. Also, the introitus is often narrow, stenotic, and anteriorly displaced with a horizontal vaginal lie (Woodhouse and Hinsch, 1997). Due to the pubic diastasis, which is predisposed to widen with growth, the labia, mons pubis, and clitoris are divergent. Deficiencies in the cardinal ligaments result in poor apical uterine support (Woodhouse, 1999). With abnormal displacement along the horizontal axis of the vagina, the uterus is predisposed to prolapse with the cervix near the introitus on the anterior wall. Current data indicate that pelvic osteotomy at the time of primary closure does not contribute to uterine prolapse with the primary influence being the width of the adult diastasis (Anusionwu et al., 2012, 2013). Indeed, a substantial issue that contributes to fertility and presents significant issues during pregnancy is POP in the BE female patient. Several single-institution series provide insight into the fate of the BE patient with regard to POP presentation with a commonly accepted incidence of 18% to 30% (Anusionwu et al., 2012; Mathews et al., 2003). The defining difference in the BE population is the accelerated pace of POP development, often independent of parity. In a series of 56 women with classic BE, 10 patients developed vaginal and uterine prolapse during the study period with a mean age of 16 years. An additional retrospective series of 52 BE female patients revealed that 52% developed POP, with 85% ultimately requiring surgical intervention (Nakhal et al., 2012). Supporting data regarding higher rates were identified in a series of BE women with continent urinary diversion, where the incidence of POP requiring surgical repair reached 38% (Rubenwolf et al., 2016).

Fertility

In general, women with BE are considered to have normal to only mildly impaired fertility, with approximately 68% of those who conceive having successful pregnancies (Giron et al., 2011). However, for patients who have previously undergone extensive pelvic surgery, experienced authors have suggested that visceral adhesions may negatively affect fertility because of uterine retroflexion and concomitant issues with conception and implantation (Hautmann and Volkmer, 2007). Of additional concern for the BE patient is the location of the cervix on the anterior vaginal wall, which may prohibit adequate semen delivery and delay fertility (Deans et al., 2012).

Pregnancy

Preconception counseling is strongly encouraged when the pregnancy is planned. Involvement of a multidisciplinary team with high-risk obstetrics, urology, and anesthesiology should be considered for consensus decision-making for the BE female desiring pregnancy. Each patient with BE presents a unique challenge for the practitioner. The myriad considerations include patient age, underlying comorbid disease, genetic implications for the offspring, pelvic bony and muscular anatomy, urinary diversion status, prior abdominal surgeries, continence, renal function, and presentation of the fetus. Appreciation of these physiologic, anatomic, and social considerations should guide the physician to optimize organization of care for these women.

Although contemporary data are lacking, the heritability of BE is estimated to effect 1 in 70 offspring (Shapiro et al., 1984). Even with sparse literature, advisement regarding the potential genetic component of BE should be provided if feasible in preconception counseling.

Tactics for management of POP during pregnancy are generally conservative, with bed rest and pessary insertion preferred and surgical management deferred until completion of childbearing (Nakhal et al., 2012). Notably, previously repaired POP in the BE female is likely to recur during pregnancy (Stein et al., 1995). Indeed, acute postpartum POP may affect nearly one-half of women with BE (Deans et al., 2012). Difficulties with intermittent catheterization via the native urethra may arise secondary to exacerbation of POP during pregnancy. Curiously, unlike expectations from the general population, the limited studies available for the BE female patient have yet to detect an association with parity and risk for persistent POP (Anusionwu et al., 2012; Ebert et al., 2009).

Additional hazards in the BE female patient include elevated risk for spontaneous abortion, which in some series reached 35% of pregnancies (Clemetson, 1958; Deans et al., 2012). In the 19 patients presented, there were 57 pregnancies (three sets of twins), which resulted in 56% live births, 35% spontaneous abortions, 2% terminations, and 7% stillbirths or neonatal deaths. Other contemporary populations of 20 BE patients reported 15% spontaneous abortion rates, similar to the general population (Dy et al., 2015). **An added concern of high acuity is the development of preeclampsia, which was demonstrated in 32% of patients in one series, predominantly occurring in women with baseline renal insufficiency** (Deans et al., 2012). Vigilance and appropriate preconception counseling are critical to inform the patient regarding the realistic details involving the relatively high rates of antenatal and postnatal complications, along with risks for fetal morbidity and mortality.

Mode of Delivery

Historically, of course some BE patients did undergo vaginal delivery, however anatomic constraints and postpartum prolapse remained a significant concern (Hautmann and Volkmer, 2007). Currently, **it is generally accepted that BE patients undergo planned caesarean delivery** with engagement of a multidisciplinary team (Dap et al., 2017; Dy et al., 2015; Stein et al., 1996; Wilby and Wood, 2015).

Before accurate counseling and planning for delivery, priority must be given to obtaining comprehensive records on prior surgical interventions and urinary tract evaluations including upper-tract studies. Although often the complete operative record will not be available for review, securing as much primary source information regarding specific procedures cannot be underscored. Individual practice patterns for pediatric reconstruction in addition to often multiple operative revisions make understanding the anatomy a priority for the urologist assuming care.

As noted earlier, for any bladder augmentation, it is preferable to perform the cesarean procedure via a high-midline or paramedian incision to avoid damage to the reservoir and augment mesentery (Hensle et al., 2004; Hill et al., 1990). Catheterization of channels in the immediate preoperative period may assist with either avoidance or recognition of injury induced by the dissection. An excellent overview of the cesarean section technique, along with discussion of one institution's best practices for pregnancy management in the BE population, is detailed in the University of Washington experience (Dy et al., 2015). Included in this compilation is the counseling that it is imperative for planning of the delivery that BE patients be counseled regarding such fetal risks and the incidence of preterm delivery with a mean gestation anticipated at 36 weeks. Of substantial concern is that an abnormal fetal presentation may be present in over one-half of BE women and requires extensive predelivery planning (Greenwell et al., 2003).

Profound risks exist for emergency cesarean section versus elective procedures, supporting the necessity for BE patient proximity to appropriate levels of high-risk obstetric care and urologic expertise to optimize outcomes for both the mother and infant (Deans et al., 2012).

Key Points

- Most patients with congenital conditions affecting the lower urinary tract have normal fertility and should have prenatal counseling.
- Complexities of pregnancy in the population with prior urinary diversion require an individualized approach.
- Mode of delivery is dependent on prior urinary reconstructions and patient preference, although in most of cases cesarean delivery is preferred for the BE patient.

Functional and Anatomic Urologic Concerns During Pregnancy

Intermittent Catheterization

Due to the expanding size of the gravid uterus coupled with frequently compromised body habitus and mobility, issues with intermittent catheterization may manifest as pregnancy progresses. These difficulties are not exclusive to compression of a continent catheterizable channel but may also present in patients utilizing their native urethra for catheterization. In one recent series of women with urinary diversions, 4 of 25 patients required an indwelling catheter during the pregnancy because of difficulties with intermittent catheterization (Huck et al., 2017).

Urinary Diversion

Due to the heterogeneous nature of the patient population, global principles of management are not feasible during pregnancy. However, series have demonstrated excellent outcomes with regard to management of the diversion patient during pregnancy.

Several manuscripts exist regarding the effect of the expanding uterus on mesenteric blood supply to an intestinal segment previously utilized for bladder augmentation or urinary diversion. Reports have noted that the pedicle supplying an ileal conduit is displaced cephalad and lateral to the expanding uterus, whereas the pedicle usually remains anterior to the uterus after augmentation cystoplasty (Gitlin et al., 2002; Schilling et al., 1996). Fortunately, it has been described in most patients that pregnancy slowly increases tension on the mesentery, leaving ample time for adaptation (Hautmann and Volkmer, 2007). Although it should always remain a consideration for delivery planning, it appears that adherence of the mesentery to the uterus is also rare (Gitlin et al., 2002; Hensle et al., 2004).

Contemporary series suggest high rates of UTI and tendency to premature delivery in the diversion patient (Huck et al., 2017). Patients without bladder neck closure may experience de novo incontinence secondary to pressure from the expanding uterus, which in most instances is expected to resolve after delivery (Hill et al., 1990). One specific caution regards the diagnosis of pregnancy in the augmented bladder. Due to false-positive readings resulting from urinary changes after interaction with the bowel mucosa, urine-based pregnancy tests are not recommended, and the use of serum human chorionic gonadotropin is preferable (Nethercliffe et al., 2001).

Continent Catheterizable Stoma

Women with continent channels may experience de novo stomal difficulties during pregnancy (Greenwell et al., 2003; Hensle et al., 2004). Such problems may be secondary to changes in body habitus, particularly if the channel is in the right lower quadrant. Enlargement of the uterus may compress and stretch the channel, making catheterization increasingly difficult during progression of the pregnancy. Such channel changes are typically expected to resolve after delivery. Alternative catheterization techniques, such as use of a coude-tip catheter, may occasionally be necessary. If the patient remains with a patent urethra and the procedure is technically feasible, use of native urethral catheterization may be indicated. Occasionally, the increased intra-abdominal pressure of the uterus can result in stomal prolapse or parastomal herniation, which again the patient may anticipate resolution after delivery.

Urinary Tract Infection and Urinary Diversion

Perhaps the most prevalent concern for patients with urinary diversion during pregnancy is the management of UTI. In the general population there is no difference in the incidence of asymptomatic bacteriuria (ASB) between pregnant and nonpregnant women. However, most patients with a continent diversion or augmentation cystoplasty can expect chronic, or at the very least intermittent, bacteriuria related to clean intermittent catheterization. ASB is often not treated, particularly in patients with bladder augmentation or performing intermittent catheterization. However, in pregnancy ASB requires intervention due to fetal risk. It is well recognized that the rate of pyelonephritis during pregnancy increases to 16% to 18% in women who previously underwent urinary diversion, and such infections can lead to preterm labor, fetal wastage, and infants small for gestational age (Hautmann and Volkmer, 2007; Vordermark et al, 1990). A similar risk profile appears to be present after augmentation cystoplasty, with several small series reporting up to 60% rates of UTI and pyelonephritis (Gitlin et al., 2002; Greenwell et al., 2003; Hill et al., 1990). Because of the potential catastrophic consequences of early pyelonephritis to the fetus, many physicians recommend use of daily antibiotics for these complex diversion patients (Thomas and Adams, 2009). Of course, the potential teratogenic effects of the antibiotic compounds must be considered with such decisions. One reasonable approach would be reserving daily antibiotic use to those patients in the highest risk categories such as those with baseline or new-onset hydronephrosis, multiple symptomatic infections, or a history of pyelonephritis before pregnancy. Other authors advocate culture surveillance and treatment only in the context of symptomatology, much as they would treat these patients outside pregnancy. This debate remains active and no consensus exists, leaving each decision to be at the physician's discretion and driven by individual patient parameters and desires.

Urologic Malignancy During Pregnancy

Although seemingly a relatively rare situation, malignancy during pregnancy occurs with an incidence of 1 in 1000 gestations (Cunningham et al., 2013b; Martin and Rowland, 2007). The most common malignancy discovered during pregnancy (1 in 5000) is breast malignancy. Management poses significant challenges of both diagnostics and interventions with regard to fetal and maternal concerns. Balancing the risks of continuation of the pregnancy, long-term maternal health, and delaying treatment requires an individualized approach that is reflected in the literature for urologic malignancy. Herein we review some potential diagnoses and proposed evolving strategies for treatment for the most common urologic malignancies during pregnancy. We encourage a multidisciplinary approach with obstetrics, medical oncology, and anesthesiology to optimize outcomes for the patient and fetus.

Many urologic issues present in an asymptomatic fashion during pregnancy because of the intense testing and screening that may uncover incidental or occult conditions. Indeed, some symptoms of more common urologic disorders, such as hematuria, flank pain, or hypertension may be attributed to more common conditions of pregnancy (Hendry, 1997).

Evaluation of malignancy is often predicated on focal or systemic imaging. As discussed in the previous section, radiation risks to the fetus must be balanced with the risk to maternal health. Mechanisms to decrease exposure and increase sensitivity for diagnosis must always be employed in these delicate situations.

One fascinating implication of malignancy and pregnancy is the status of the immune system during these seemingly disparate conditions. Indeed, pregnancy and malignancy are select and unique conditions in which highly antigenic agents are tolerated by the immune system (Beaman et al., 2016). It is believed that **in most cases, pregnancy does not change the biologic properties or progression of tumors,** but data is lacking. There is sparse information regarding pregnancy and urologic malignancy risk in the immunocompromised patient to guide counseling.

Renal Tumors

The most common urologic tumor described during pregnancy is renal cell carcinoma. Analogous to the situation encountered with nonpregnant patients, the primary symptoms at presentation include pain, hematuria, hypertension, and/or a palpable mass (Gladman et al., 2002). However, in the pregnant patient, identification of renal tumors may be delayed because of the low index of suspicion for renal malignancy combined with myriad additional indications for presentation with this symptom complex.

Outside of known risk factors such as tobacco use and genetic syndromes such as Von Hippel-Lindau disease, which may increase a patient's overall risk for development of renal cell carcinoma, **the specific physiologic stresses of pregnancy have not been determined in a causal relationship to development of renal cell carcinoma.** Disparate evidence regarding parity, hormonal status, and subtype of renal cell carcinoma has been presented without consensus (Khaled et al., 2016). Evaluation should minimize risk to the fetus, but accurate staging for determination of treatment is mandated. In conjunction with the American College of Radiology and the American Institute of Ultrasound in Medicine, the American College of Obstetricians and Gynecologists issued a committee opinion regarding optimal utilization of diagnostic imaging during pregnancy (Committee on Obstetric Practice, 2017b). Although ultrasonography and MRI are not associated with fetal risk and remain the techniques of choice in the pregnant patient, CT scan can be performed at a radiation dose range lower than the exposure associated with fetal harm. Either CT or MRI contrast-enhanced abdominal imaging is recommended by AUA guidelines for characterization of the renal mass, renal morphology, and evaluation of other abdominal organs and visceral metastases (Campbell et al., 2017).

Iodinated intravenous contrast agents administered for soft tissue enhancement during CT can cross the placenta and enter fetal circulation, although animal studies have not demonstrated teratogenic or mutagenic effects from administration (Webb et al., 2005). However, use of gadolinium-based agents for enhancement with MRI during pregnancy remains controversial, with administration limited to situations in which the benefits clearly outweigh the possible fetal risks (Ray et al., 2016). Therefore, when possible, use of CT imaging in the pregnant patient is likely preferred when contrast enhancement is required in the setting of staging urologic malignancy.

As the diagnosis in pregnant patients remains rare, a potential role for renal mass biopsy is present if there is a suspicion the radiologic finding may be hematologic, metastatic, inflammatory, or infectious (Campbell et al., 2017). In the setting of renal malignancy in the predominantly young pregnant patient, AUA guidelines suggest recommending genetic counseling to determine the presence of a familial renal neoplastic syndrome.

Case reports of tumor characteristics, clinical staging, and ultimate management strategies dominate the literature for renal cell carcinoma during pregnancy (Khaled et al., 2016). Engagement of a multidisciplinary team is mandated to direct appropriate therapy and define the expected risks to the fetus and provide guidance when termination of the pregnancy may be advisable. Management is like that for the nonpregnant patient, with the mainstay of treatment being nephron-sparing or radical nephrectomy, with timing to proceed ultimately dependent on the clinical status of the patient and the trimester of pregnancy. The approach must be tailored to the specific tumor and the comfort of the surgical team, with attention to the general considerations in the pregnant patient outlined earlier in this chapter.

A new paradigm for systemic therapy for metastatic renal cell carcinoma has emerged with the advent of multikinase inhibitors, mTOR inhibitors, antiangiogenic agents, and immunotherapies. In general, the safety of these agents during pregnancy is poorly characterized, with most agents avoided during pregnancy because of direct evidence of human fetal risk.

Angiomyolipoma

Benign renal tumors such as angiomyolipoma (AML), one-half of which are not associated with tuberous sclerosis complex, are the second most common renal tumor and primarily asymptomatic. However, in situations of spontaneous rupture, patients may present with hematuria, flank pain, and life-threatening retroperitoneal hemorrhage (Myoen et al., 2015). Although rare, the hormonal environment, vascular volume, and increased abdominal pressure may predispose to rupture in the pregnant patient. In review of 45 cases of ruptured AML during pregnancy, average tumor size was determined to be 9.6 cm. Approximately one-half of the cases presented as hemodynamically stable, with 91% of these women completing pregnancy with a term delivery. However, in unstable patients, fetal death occurred in 30%. With the substantial risk, benefits of imaging, especially serial imaging for women choosing observation, outweigh fetal risks. Outside of urgent surgical interventions, treatment of choice includes transarterial embolization, even with the associated risk for premature labor secondary to postembolization syndrome (Martin and Rowland, 2007).

Bladder Tumors

Fortunately, bladder cancer is exceedingly rare in pregnant patients, although case reports exist of transitional cell carcinoma, adenocarcinoma, squamous cell carcinoma, and benign leiomyoma (Mizuno et al., 2003; Spahn et al., 2005). **Typically, patients present with hematuria, which is estimated to be misdiagnosed as vaginal bleeding in 22% of pregnant women**. Obtaining a catheterized urine specimen is preferable in these situations to assist with source determination. Lower urinary tract symptoms such as urgency, frequency, and nocturia are common during pregnancy and may not raise concern for bladder malignancy in the otherwise young and low-risk population of pregnant women (Cardozo and Cutner, 1997).

Most case reports in the literature of bladder malignancy during pregnancy reflect general expectations of predominantly urothelial carcinoma, and most display nonmuscle invasive pathology (Spahn et al., 2005). Squamous cell carcinoma, traditionally associated with schistosomiasis, has been reported in three cases during pregnancy marked by aggressive disease and poor prognosis despite radical cystectomy (Alleemudder et al., 2016; Church and Dieh, 2013; Spahn et al., 2005).

Diagnosis and management of bladder cancer during pregnancy requires complex orchestration of disciplines and delicate balance of maternal and fetal risks. In general, adherence to AUA guidelines for management of non–muscle-invasive bladder cancer (NMIBC) and muscle-invasive bladder cancer are not always completely feasible during pregnancy depending on the stage of the patient and considering fate of the fetus (Chang et al., 2016, 2017). As mentioned earlier, the presence of hematuria during pregnancy should be evaluated per standard of care with cystoscopic evaluation combined with appropriate upper-tract imaging (Davis et al., 2012; Sandhu et al., 2009). Imaging requirements are predicated on diagnostic modalities appropriate for evaluation of urologic malignancy, which is primarily with CT scanning. Indeed, modalities such as ultrasound, which are generally accepted as safe imaging techniques in pregnancy, may only provide diagnosis in 52% of cases to date (Spahn et al., 2005).

Transurethral resection may be safely performed at any time during gestation to obtain a pathologic specimen to guide further treatment (Pais and Reinstatler, 2018). Further imaging for staging and metastatic evaluation will often be mandated. For most NMIBC, further treatments after endoscopic resection may be deferred until after delivery. One study documents utilization of bacille Calmette-Guérin immunotherapy during pregnancy without known adverse outcomes to the fetus; however this adjuvant therapy should be generally avoided because of the potential for systemic side effects and both maternal and fetal harm (Wax et al., 2002). Likewise, for intravesical mitomycin C, balancing this risk to the fetus with the potential benefit of adjuvant therapy must be carefully assessed for the pregnant bladder cancer patient, and in most instances, administration can be delayed until after delivery.

Muscle-invasive bladder tumors in pregnancy reported to date in the literature suggest overall poor prognosis (Spahn et al., 2005). No standard treatment strategy exists for this vulnerable population, and there is scare data supporting any specific treatment. Certainly, depending on the trimester at diagnosis, extent of disease, and individual desires of the additional stakeholders, definitive therapies with neoadjuvant chemotherapy and radical cystectomy may be timed to the nuances of the situation.

Management of Urinary Tract Infections in Pregnancy

A critically important aspect of urologic management of the pregnant patient includes understanding of the pathophysiology and potential complications of ASB recommendations with detailed analysis available elsewhere in this volume (see Chapter 55).

ASB is generally discovered in 2% to 7% of women during pregnancy (Nicolle et al., 2005; Patterson and Andriole, 1987). Historical data and contemporary systematic review confirm with moderate quality evidence that antibiotic treatment of ASB during pregnancy likely reduces the risk for progression of infection to pyelonephritis (Smaill and Vazquez, 2015). As described earlier (see Physiologic Changes During Pregnancy), a myriad number of anatomic and physiologic alterations progress during pregnancy that may affect the natural history of bacteriuria and subsequent progression to pyelonephritis (Davidson and Talner, 1978; Patterson and Andriole, 1987; Waltzer, 1981).

Indeed, in pregnant patients with untreated ASB, pyelonephritis may occur at an incidence of 15% to 45% (Pedler and Bint, 1987; Wright et al., 1993). Most women experience episodes of pyelonephritis when hydronephrosis and urinary stasis are most prominent in the third trimester (Cunningham et al., 1973). Approximately one-third of pregnant women who develop pyelonephritis have a documented prior history of pyelonephritis (Gilstrap et al., 1981).

Pyelonephritis during pregnancy, in addition to the potential sequela to the mother, places the fetus at risk, with suggestion that ascending urinary infections may contribute to up to 50% of premature deliveries, particularly before 30 weeks' gestation (Cunnington et al., 2013). **Because pregnant patients with ASB remain at higher risk for development of symptomatic lower or upper UTIs, which may precipitate adverse fetal outcomes such as decreased birth weight and premature labor, consensus opinions indicate that pregnant patients should be screened for ASB and positive cultures should be treated** (Nicolle et al., 2005; Nicolle LE 2018; US Preventive Services Task Force, 2008).

The increased likelihood that ASB may progress to acute pyelonephritis during pregnancy alters the morbidity of bacteriuria for this group. Treatment of

ASB in pregnancy likely decreases the incidence of acute pyelonephritis during pregnancy to 1% to 4% and reduces the potential for preterm birth and low birth weight (Smaill and Vazquez, 2015).

Therefore, contemporary recommendations include routine screening of all pregnant women for bacteriuria. **It is suggested that screening by urine culture be obtained at 12 to 16 weeks' gestation** (Nicolle et al., 2005; Nicolle LE, 2018; US Preventive Services Task Force, 2008). Currently, insufficient evidence exists regarding recommendations for repeat screening in women with initial negative cultures or those who underwent treatment for ASB.

As mentioned earlier, the guidelines are reflective of data suggesting that treatment of ASB can reduce morbidity and complications in pregnant patients. However, selection of an appropriate antimicrobial agent must be made in multidisciplinary collaboration to ensure optimization of safety and strategy for the mother and fetus (see General Concepts of Urologic Medication Administration during Pregnancy earlier in this chapter). In general, bacterial composition during pregnancy appears similar to that seen in nonpregnant patients (MacDonald et al., 1983). In general, beta-lactam antimicrobials such as ampicillin or cephalexin are considered safe and generally effective throughout pregnancy. In patients with penicillin allergy, nitrofurantoin is a reasonable alternative. If nitrofurantoin is used, however, it is discontinued at 35 weeks' gestation because of an increased risk for hemolytic anemia in the neonate.

With regard to duration of therapy for ASB, a recent systematic review included 1622 women and compared single-dose to short-course (4 to 7 days) antimicrobials (Smaill and Vazquez, 2015; Widmer et al., 2015). In this analysis, there was a trend toward diminished bacteriuria clearance in the single-dose regimen, however the optimal duration of therapy will ultimately be antimicrobial specific.

Pregnant patients with acute pyelonephritis should be hospitalized and treated with parenteral antimicrobial agents until clinical improvement occurs. More than 95% of these patients respond within 24 hours after administration of ampicillin and an aminoglycoside (Cunningham et al., 1973) or cephalosporins (Sanchez-Ramos et al., 1995). Parenteral treatment should be tailored on the basis of culture sensitivities before transitioning to oral antibiotics. If index of suspicion is elevated for obstructive pathology or clinical improvement is not rapid, further investigations with imaging are prudent. For outpatient therapy, culture-specific oral agents should then be given for at least 14 days (Faro et al., 1984). After completion of the treatment course, low-dose prophylaxis may be considered in select cases for prevention of reinfection (Sandberg and Brorson, 1991; Van Dorsten et al., 1987).

Urologic Management of Placental Abnormalities

One of the most ominous consultations for urology remains assistance with acute management of placental invasion involving the urinary tract. **Disorders of invasive placentation is the umbrella term to encompass the three levels of morbid placental attachment to or beyond the uterine wall secondary to invasion of the trophoblast into the myometrium** (Jauniaux et al., 2017). The three commonly referred terms used to describe the extent of invasion include *placenta accreta, increta,* and *percreta,* although *placenta accreta* is classically utilized in reference to the entire spectrum of placental invasion disorders. Failure of the placenta to separate normally from the uterine wall or invasion into adjacent organs is typically accompanied by the risk for exceptional, life-threatening hemorrhage and coagulopathy, with an average blood loss between 3000 and 5000 mL at delivery in women with placenta accreta (Hudon et al., 1998). Maternal mortality with placenta accreta has been reported as high as 7% and may occur despite optimal planning and transfusion management (Committee on Obstetric Practice, 2012; O'Brien et al., 1996). Prior caesarean delivery appears to be the predominant risk factor in contemporary series resulting from abnormal implantation in the myometrial scar with compromised vascularity (Jauniaux and Jurkovic, 2012). Advanced maternal age is additionally contributory, with women over 35 years of age accounting for 57% of placental adhesive disorders (Fitzpatrick et al., 2012). Current epidemiologic studies report an overall incidence of placenta accreta in the United States of 1 in 533 deliveries (Wu et al., 2005). Used as a singular term, a *placenta accreta* occurs when the placenta attaches to, but does not invade into, myometrium. When chorionic villi invade the myometrium, the condition is termed *placenta increta*. Most commonly **encountered by urology is the most severe form, *placenta percreta,* in which the chorionic villi have perforated the full thickness of the myometrium and breached the uterine serosa with possible adherence to surrounding organs such as the bladder, ureters, and rectum** (Wortman and Alexander, 2013).

Diagnosis and presentation of placental attachment disorders is highly heterogeneous, but the value of accurate predelivery assessment for multidisciplinary planning is immeasurable. With regard to urology-specific concerns during gestation, it is estimated that approximately 25% of women with placenta percreta will display hematuria (Konijeti et al., 2009). With knowledge of the potential risk factors for abnormal placentation, the clinician may choose to proceed with cystoscopic evaluation of such patients to evaluate the posterior bladder wall and significant invasion (Ibrahim et al., 2015; Liu et al., 2018; Takai et al., 2005). Biopsy of the hypervascular tissue visualized in the bladder is discouraged. Standard diagnostic modalities employed for evaluation of placental disorders with regard to imaging include grayscale ultrasonography, which displays sufficient sensitivity and specificity to establish an appropriate anatomic view of the abnormal placentation (Comstock et al., 2004). Adjunct utilization of MRI may be considered when ultrasound findings are inconclusive or invasion into regional vasculature or adjacent organs, such as the ureter, requires further delineation (Committee on Obstetric Practice, 2012).

Once placenta percreta is recognized, which ideally will occur at a significant time before delivery, assembly of a multidisciplinary team is the currently recommended standard of care to reduce maternal and fetal morbidity and mortality. Suggested involvement includes an appropriate anesthesiologist, obstetrician, experienced pelvic surgeon such as a gynecologic oncologist, intensivist, maternal-fetal medicine specialist, interventional radiologist, and as required, additional surgical subspecialties such as urology and general surgery (Eller et al., 2011). These initiatives are optimally accommodated at specialized tertiary centers where support personnel and intensive care is available and criteria for centers of excellence for management of placenta accreta have been outlined (Silver et al., 2015).

Recommended management generally involves planned preterm caesarean hysterectomy, which implies caesarean delivery with the placenta left in situ combined with hysterectomy. Optimal maternal and neonatal outcome in stable patients has been demonstrated with a planned delivery at 34 weeks’ gestation, often accompanied by carefully orchestrated administration of antenatal corticosteroids to facilitate fetal lung maturation (Committee on Obstetric Practice, 2012). However, delivery timing is individualized depending on patient preferences and clinical circumstances. Planned delivery to diminish blood loss and complications is the goal, but contingency plans for emergency should be outlined. Substantial morbidity is associated with unsuspected placental abnormalities at the time of delivery with the surgeon attempting removal of the adherent villous tissues (Warshak et al., 2010). Conservative management options have been explored for women with a strong desire for future fertility that entail leaving the placenta in situ after delivery to reduce operative blood loss and potentially preserve the uterus, although delayed hysterectomy is the most common outcome (Jauniaux et al., 2017; Skinner et al., 2012). Even with adjuvant therapies such as uterine artery embolization, methotrexate therapy, hemostatic sutures, pelvic devascularization, and balloon tamponade, there may be substantial delayed bleeding and infection, and the role of such management remains uncertain.

Preoperative planning by the urologist should include appropriate counseling of the patient with regard to placement of ureteral catheters or stents and potential manifestations of substantial injury or need for extirpative surgery for urologic organs and urinary diversion. Exceptionally distorted anatomy and abnormal vasculature places genitourinary organs at significant risk for inadvertent injury during caesarean delivery and/or hysterectomy, with overall rates estimated at 29% (Tam et al., 2012). Retrograde cystoscopic placement of ureteral catheters will facilitate ureteral identification and/or intraoperative injury (Jauniaux et al., 2017; Matsubara et al., 2013). If plans entail delayed hysterectomy because of intraoperative findings during caesarean delivery, conversion to indwelling double-J stents may be preferred if feasible based on the clinical situation. Additionally, up to one-third of women who undergo peripartum hysterectomy may require reexploration, and indwelling stents may be useful during these procedures to control of bleeding or genitourinary tract injury.

Many placenta percreta cases involve invasion of the detrusor muscle, but even with substantial uterine bleeding, bladder preservation should be attempted. For known invasion, planned cystotomy and partial cystectomy may reduce intraoperative complications as attempts to develop a plane to separate the placenta from the bladder may result in substantial hemorrhage (Konijeti et al., 2009). Patients should additionally be counseled regarding potential long-term sequela of damage to the urinary tract including fistula, incontinence, and neurogenic dysfunction.

Key Points for Management of Placental Abnormalities

- Ultrasound imaging is superior to MRI for routine screening of placenta accreta in at-risk patients, but the degree of invasion to adjacent pelvic tissues and organs may be better ascertained with MRI.

- Optimum timing for planned delivery for a patient with suspected placenta percreta is approximately 34 weeks.
- Patients who are diagnosed antenatally with placenta percreta should be referred to a tertiary care center and managed by a multidisciplinary team that includes urologists, general surgeons, obstetric anesthesiologists, interventional radiologists, and intensivists.
- Urologists should carefully counsel patients regarding complexities of management and outcomes for urinary tract injury and should consider retrograde catheter placement to prevent or identify ureteral injury.

Acknowledgments

For the exceptional expertise of Camille Ivey, Liaison Librarian for Health Sciences at Vanderbilt's Eskind Biomedical Library, for outstanding methodologic assistance with literature search and evaluation.

Intraoperative Consultation

Michael J. Schwartz MD, FACS, Jessica E. Kreshover MD, MS

Surgery can be unpredictable. Although there are certainly known preoperative factors that influence the degree of difficulty of a given surgery, unanticipated intraoperative findings, technical errors, and complications can occur regardless of the level of preparation of the surgical team. Intraoperative challenges present themselves in all surgical disciplines, requiring urgent intraoperative involvement of colleagues with expertise that the primary surgeon may not have. Intraoperative consultations fill this need.

Intraoperative consultations in urology span a wide range of disease processes, iatrogenic injuries to the genitourinary system, and trauma. As noniatrogenic genitourinary trauma management is covered extensively elsewhere in this text, this chapter focuses on intraoperative consultations outside of the trauma setting.

This is the first edition of this text to include a section on the topic of intraoperative consultations. Although not commonly covered in a formal didactic setting, precepts used in managing intraoperative consultations are familiar to most urologists. These principles are, at their core, the same that urologists strive to apply in day-to-day practice, albeit in circumstances that may be unique or unforeseen. Herein lies the challenge. As with any surgery, the intraoperative consultation requires the urologist to draw from accumulated experience gained through training and practice and apply judgment. **Applying good judgment and adherence to ethical tenets in unanticipated or inconvenient situations distinguishes a well-managed intraoperative consultation.** Here, we formally summarize management of intraoperative consultations in urology.

Intraoperative consultations occur daily and are defined as a call from the primary surgeon to a colleague for help, either within the same discipline or from another medical field. Consultations may occur because of iatrogenic injuries, unexpected findings, or the need for additional unanticipated surgery. Although a general discussion of unexpected findings may have taken place, the specifics of most unanticipated findings or change in surgical plan will not likely have been explicitly discussed with the patient as these occurrences are, by definition, unexpected. The role of the consulting urologist may also be highly variable. For example, the consulting urologist may entirely take over the remainder of a surgery if his or her skill set is most appropriate to manage the remainder of the procedure. However for some consultations, simply providing advice or guidance may be all that is necessary if the primary surgeon has all of the necessary skills to continue but needs a second opinion about how to proceed. One of the most routine examples of intraoperative consultation in surgery (which is often anticipated) is for help from our pathology colleagues. Intraoperative examination of tissue can be critical in determining the best surgical management of many malignancies or to determine if abnormal-appearing tissue is malignant in cases of unexpected operative findings. This chapter will focus on the urologist as the consultant and the wide range of reasons that we may receive the “call for help.”

Each intraoperative consultation is unique in both its scope and challenges. In most instances, the consulting urologist will not have any prior relationship with the patient. This limits the ability to gather a history that may be critical in decision making that may have permanent impact on a patient's medical condition or quality of life. At the time of the consult, the patient is most vulnerable—unconscious and unable to participate in discussions of how to address the situation. Some intraoperative consultations may be very straightforward, and others have a baseline level of complexity well above the majority of surgical cases.

Injuries to the genitourinary tract recognized in the postoperative setting are often associated with severe morbidity, and their management is far more complex than those recognized immediately at the time of surgery. For this reason, although it may be inconvenient at times, being called into the operating room to address a recognized injury during surgery is a blessing for all involved including the primary and consulting surgeons, but most importantly the patient. A recognized injury may be interpreted by some as a careless mistake and, at times, that may be true. However, identification of injury to the genitourinary tract at surgery may also represent vigilance and maintenance of a high degree of suspicion for such injury on the part of the primary surgeon. Calling for help is often a sign of integrity and is an act with the interest of the patient at its core (Langerman et al., 2014). When being called to the operating room for consultation, it should also be remembered that injuries are at times unavoidable or even intentional when it serves the interest of the patient (such as with a goal of oncologic cure). It should be regarded as an honor to be asked to help.

Ethical Considerations

The Patient-Physician (and Family-Physician) Relationship

Upon acceptance of an intraoperative consultation, the consulting urologist enters the patient-physician relationship (Langerman et al., 2014). Some of the most critical portions of the intraoperative consultation are not necessarily the procedure involved, but how the decision is made about what to do when there is a life-impacting choice at hand. Information gathering after receiving the call and discussions with family members during, and with the patient after, surgery are critical (Aubrey et al., 2014). If decisions are to be made during surgery, **full disclosure regarding the reason for the intraoperative consultation is imperative for the family or other surrogate to be able to make informed choices concerning the next course of action**. If the patient is stable, it may be best to have family discussions with both the primary surgeon and the consulting urologist present. Anecdotal evidence suggests that these discussions help to shape the new patient-physician relationship and build trust with the patient, even though the patient does not become aware of the intraoperative events or discussions until after the fact (Langerman, et al., 2014; Wu et al., 1997). The process of bringing as many stakeholders as possible to the table for discussion during surgery and before decisions are made minimizes the element of surprise that may otherwise accompany unexpected findings at surgery. These discussions contribute to the family's or surrogate's sense of transparency from the surgeon and consultant. Early and consistent communication helps the patient and family understand the condition being addressed and, of vital importance, helps set expectations surrounding recovery from surgery and any impact on day-to-day functions and quality of life. As the consulting urologist may also become either a secondary or primary physician for follow-up care, establishing trust early with the patient and family members is a standard that all should strive to achieve.

Decision Making

Intraoperative decision making, for the majority of consults, tends to be relatively straightforward. However, occasions will arise with extreme complexity of circumstance that leave no clear plan that is without significant risk or consequence for the patient. Regardless, the urologic consultant will inevitably fill the role of making an assessment and plan. Altering (or not altering) the surgical plan, aborting the procedure, or incorporating additional procedures are all options for consideration. Once an initial intraoperative assessment has been made, it is the role of the consulting urologist to discuss options for proceeding with the primary surgeon, anesthesiologist, and family members or other surrogate (Fig. 19.1). The simple act of discussing alternatives with these stakeholders can often bring forward a clear choice and make an otherwise difficult decision much more comfortable if all are in agreement. Calling colleagues for advice in such situations can also be tremendously helpful in confirming that all potential options are considered. The most important stakeholder—the patient—is unable to participate in decision making, a fact critical to recognize and respect as the consultant. Decisions made during an intraoperative consultation may be of no major consequence to the patient, or potentially may be life-altering and irreversible. As the consulting surgeon will most likely not have a prior relationship with the patient, the downstream consequences of acting intraoperatively or deferring definitive action to a later date must be carefully considered.

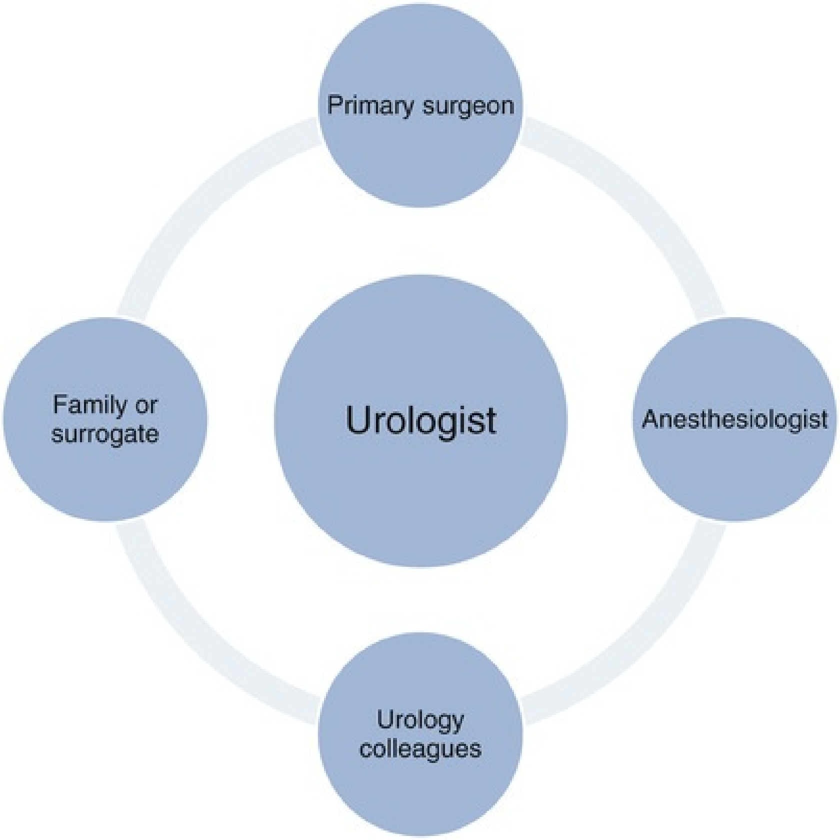

FIG. 19.1 Intraoperative decision-making stakeholders.

Similar to many challenges in medicine, the repercussions and complexity of our choices exist on a spectrum. For example, placing a stent to address a low-grade ureteral injury has low morbidity, would be unlikely to have long-term consequences, and is a reversible intervention. Most reasonable urologists would proceed when called on without the need to hold intraoperative discussions with the patient's family or awaken the patient to allow the patient to be made aware of and consent to the additional procedure. Disclosure of such intervention to the patient and family members nonetheless remains a critical component of the intraoperative consultation and postoperative care. Performing a more major reconstruction to address a complex proximal high-grade ureteral injury, not amenable to ureteroureterostomy, requires consideration of procedures that are either irreversible, hold much higher potential morbidity, or both. The innate characteristics and complexity of these reparative options warrant patient participation. However, the patient's right to decide must also be weighed against the possible harm of a delayed repair, second anesthesia, increased difficulty associated with reoperation, and compounding effect on recuperation time. In selected cases, complex repair during intraoperative consultation should be considered if the harm of deferring outweighs the benefits. **When considering whether or not to temporize or attempt definitive action at intraoperative consultation, current patient condition, procedure morbidity, long-term consequences, and reversibility should all be thoroughly considered. In general, options for any complex reconstruction may drastically differ in how they may or may not affect quality of life, and, with selected exceptions, are best deferred with temporizing measures until such time that the patient is able to participate in shared decision making.**

Surrogate decision makers may not always be present or reachable at the time of an intraoperative consultation when a choice must take place. It must also be remembered that the family member or other individual accompanying the patient at the hospital may or may not be an appropriate person to act on the patient's behalf if a complex intraoperative decision is to be made. Most hospitals will ask surgical patients to designate an individual as a surrogate before a planned operation. This practice can minimize guesswork and help gather additional information regarding patient preferences that can inform intraoperative decisions. However, it must be considered that surrogates may make decisions contrary to patient wishes, which can have consequences for the relationship between the patient and his or her surrogate, but also for the physician and the patient, especially if the recovery is fraught with complications (Langerman et al., 2016). Also, emergencies or other circumstances may arise when a surrogate has not been designated and it falls to the physician to act in a manner representing the patient's best interest.

Disagreements may arise between the primary and consulting surgeon about how to proceed during a given consultation. These situations may increase the tension already present during an intraoperative consultation when unexpected findings or iatrogenic injury increase the complexity of the surgery at hand. When such conflicts arise, the consulting surgeon should defer to the primary surgeon's judgment in most situations, as the primary surgeon holds a preexisting relationship with the patient (Langerman et al., 2014). However, when called for help, the expertise and skill set of the urologist are fundamentally unique from the primary surgeon's in most circumstances, and the consulting urologist should proceed in the best interest of the patient if deferring to the primary surgeon is deemed potentially harmful to the patient. Fortunately, the primary surgeon will defer to the consultant's expertise in most scenarios, but if disagreement persists, escalating the dispute to the department chairs or hospital medical director may be appropriate.

Ultimately, the decision maker at intraoperative consultation is the consultant. Gathering information from the medical record, imaging, and from all interested parties including the primary surgeon, patient surrogates, anesthesiologist, and colleagues, can inform intraoperative decisions. However, no other party among those in the group has the expertise and skill set to address a urologic issue other than the urologist. Acting in a manner as consistent as possible with what is perceived to be the patient's best interest while balancing the risks and benefits of the intervention will provide optimal chances of a favorable outcome.

Documentation

There may be temptation to editorialize when it comes to documenting the events of an intraoperative consultation. This may stem from an innate desire as physicians to explain why an event may have occurred—in other words, to make a diagnosis regarding the cause of the event. This is not to say that documenting a diagnosis as to the cause of an intraoperative consultation is not appropriate. For example, noting a urethral stricture as a cause for a difficult catheter passage is appropriate; there are directly observable findings that are fact-based and are appropriate to record. In addition, documenting communication regarding cause of an intraoperative injury from the primary surgeon may also be appropriate if it is fact-based and important to the management of the patient. For example, if the primary surgeon noted that the ureter was injured with cautery versus cold shears, this may change the management plan and if directly observed, should be documented. However, guessing at the cause of iatrogenic injury or laying blame at the feet of a colleague serves no medical purpose and does not rely on fact. Describing an injury as “careless” or “avoidable” in an operative dictation is in and of itself careless and avoidable—there is no room for conjecture or assignment of blame if an injury occurred.

When documenting an intraoperative consultation, it is critical that the consulting surgeon make as complete an assessment as possible. This includes scrubbing in to the surgery and creating a note summarizing the intraoperative findings. Relying on the primary surgeon to assess and document either his or her own assessment or the assessment of the consulting urologist is irresponsible and incomplete. Even if no injury is seen or no intervention is needed on the part of the consultant, **the primary observations of the consultant are critical to the medical record, and lack of documentation leaves the consultant vulnerable to legal action** (Morris et al., 2003).

Key Points

- The intraoperative consultation enters the physician into a new patient-physician relationship, and full disclosure regarding the reason for consultation is critical.

- When possible, all relevant stakeholders should be included when difficult intraoperative decisions are to be made.
- When considering whether or not to temporize or attempt definitive action at intraoperative consultation, current patient condition, procedure morbidity, long-term consequences, and reversibility should all be thoroughly considered.
- Complex reconstructions, with selected exceptions, are best deferred with temporizing measures until such time that the patient is able to participate in shared decision making.
- Documentation of intraoperative consultations should be fact-based and include the consultant's primary observations and assessment.

Surgical Time Out

In many countries around the world, a preoperative checklist—widely referred to as the “surgical time out”—is used as part of a universally applied protocol meant to increase patient safety and reduce medical errors. The role of a surgical time out for an intraoperative consultation is not clearly defined as is the case for the primary surgery taking place. It is also the case that the consulting urologist may not necessarily be able to ascertain what procedure is to be undertaken, if any, as part of the intraoperative consultation or what supplies are to be needed without gathering critical information that may not be possible without exploring the existing surgical field. Therefore, a traditional time out is typically not feasible before the urologist becomes involved with the procedure. However, once the urologist is satisfied with the information at hand and any necessary discussions with family members have taken place, there is opportunity to review the plan with everyone in the operating room similar to the traditional time out (Table 19.1). One critical piece of information that should be discussed and that is not part of the standard “time out” is the patient condition. As the condition of the patient may be highly variable at the time of the consultation, this should be reviewed, along with the patient's ability to tolerate the additional procedure. Although the patient condition would have likely been considered by the consulting urologist before deciding on the next course of action, inclusion in the time-out procedure ensures its review by the entire team and reaffirms the plan.

TABLE 19.1

Suggested Time-Out Procedure for Intraoperative Consultation

- Introduction of all staff in the operating room
- Patient identification (name, medical record number, date of birth)
- Current condition of the patient as per anesthesiologist and primary surgeon
- Name of the procedure to be performed
- Review and confirmed availability of necessary instrumentation with operating room staff
- Fluids for the operative field
- Estimate of blood loss and expected additional operative time
- Concerns not already addressed
- Verbal agreement and acknowledgement of plan by all staff in the room

Urethral Injury

Catheterization-related injuries to the urethra in the operating room are common in men. Urethral catheterization is performed across all medical disciplines by individuals with highly variable levels of experience with this procedure. Urethral stricture disease, prior surgery or pelvic radiation therapy, benign prostatic hyperplasia, and operator experience are all common contributors to failed catheter placement or urethral injury. Fortunately, the majority of these cases are handled fairly quickly and without significant consequences for the patient. Occasionally, however, urethral injury related to attempted catheter insertion may have substantial consequences including deferment of the planned primary surgery, voiding dysfunction, prolonged gross hematuria, acute renal failure, urethral stricture, or prolonged catheterization. Although relatively mundane, iatrogenic catheter-related injury to the urethra can add significantly to the cost of a patient's hospitalization and length of stay (Davis et al., 2016). As the period involving catheterization is extremely relevant to development of bacteriuria and catheter-associated urinary tract infection, iatrogenic injury is of particular concern for hospitals as reimbursements may be directly affected by such events. Much less common, urethral injuries from catheter placements may require other surgical intervention if the injury is more severe.

Difficult catheter consults plainly illustrate the importance of ascertaining the patient medical history as part of the intraoperative consultation. History of prior cystoscopic or abdominal surgery, prostate cancer, prostatectomy, radiation therapy, requirement for anticoagulation, and knowing the planned surgery are all relevant and guide management. Choice of catheter, need for cystoscopic placement, and risk associated with possible suprapubic catheterization, if necessary, are all influenced by this history.

Urethral injury may also occur during female pelvic reconstructive surgeries and may occur with concomitant bladder or ureteral injury, markedly raising the complexity of the repair required.

Incidence

The incidence of catheter-related iatrogenic urethral injuries in the operating room setting is unknown. However, reports evaluating the incidence of catheter-related injury in hospitalized patients show it to be between 3.2 and 6.7 injuries per 1000 male patients catheterized. (Davis et al., 2016; Kashefi et al., 2008). In addition, complications of Clavien-Dindo grade 2 or higher occur in up to 81% of men suffering iatrogenic urethral injury (Davis et al., 2016). Although not every iatrogenic urethral injury occurs in the operating room, in a busy hospital where tens of thousands of surgical cases are performed each year, consultations for catheter-related urethral injury are commonplace.

Mechanisms

Iatrogenic injuries to the male urethra most commonly occur as a result of tortuous urethral anatomy or benign prostatic enlargement in combination with inexperience of the individual attempting catheter insertion. Injuries are related to inadvertent inflation of the catheter balloon within the urethra or creation of a false passage with the catheter tip by trying to force the catheter into the bladder (Thomas et al., 2009). Female urethral injuries are far less common as the urethra is much shorter and does not have a tortuous course, and there is little risk for encountering stricture disease. Iatrogenic injury of the female urethra may occur in female pelvic reconstructive surgeries such as sling placement or prolapse repair.

Diagnosis

The diagnosis of urethral injury related to catheter placement is often straightforward with a history of failed catheter insertion with or without blood per urethra or within the catheter at the time of attempted placement. Cystoscopy may be performed to assist in diagnosis and to gauge the extent of injury. Intraoperative retrograde urethrography could also be used in assessment although would generally be more valuable in the trauma patient as the mechanism of injury may be more likely to cause disruption and require urethroplasty in that setting.

Iatrogenic injury to the female urethra during reconstruction will most often be recognized by cystoscopy, which is often performed precisely with the purpose of identifying injury to the bladder or the urethra. Visualization of a trocar passed for mesh placement or mesh itself within the urethra are obvious signs of injury. More subtle findings may include tethering of the urethra or bladder neck, which may indicate trocar or mesh placement through the walls of the lower urinary tract without penetration into the lumen. Other findings indicating injury during reconstructive surgery include visualization of a urethral catheter through an inadvertent urethrotomy created while dissecting between the anterior vagina and the posterior urethra.

Management

Male urethral injuries related to urethral instrumentation typically require either a specific choice of catheter or cystoscopy-guided catheter insertion to allow for successful placement. Similar to the trauma setting, a single attempt may be made to blindly place the catheter by the urologist, but if this fails, use of cystoscopy to visualize the urethral lumen and introduce a guidewire into the bladder is recommended. If the extent of stricture disease or urethral injury is too significant to allow for safe catheter insertion, percutaneous or open insertion of suprapubic catheters should be considered. The duration of catheterization after injury depends on the extent of injury, need for concomitant urethral dilatation at the time of catheter placement, and patient condition in the postoperative setting.

Urethral injuries unrelated to catheterization are rare. Unlike the bladder and ureters, which are in the operative field for many abdominal and pelvic operations, the urethra is not. For this reason, surgeries with likelihood of urethral injury are limited mainly to pelvic reconstructive surgery with a transvaginal or transperineal approach.

With a vaginal approach used in many operations for pelvic reconstruction, risk for fistula formation is an important concern when approaching repair of urethral or bladder injury in the female patient. Interposition of peritoneum, omentum, or labial fat between the anterior vaginal wall and the bladder or urethra should be considered in cases with a high anticipated risk for fistula formation.

Bladder Injury

There is significant overlap between the background, evaluation, and management of bladder injuries in the intraoperative setting and in the trauma setting. It is prudent for readers to also review Chapter 133 to familiarize themselves with bladder trauma. This section will focus on iatrogenic injury and its management. Some of this will overlap with what is delineated in Chapter 133.

Incidence

The bladder is the most commonly injured organ during pelvic surgery (Gomez et al., 2004). The pelvis, unlike the abdomen, is a fixed space—a factor that can increase the risk for bladder injury during pelvic surgery because of challenges of exposure, retractor placement, and small working space. Anatomic distortion from tumor mass effect, prior surgery or radiation therapy, or any combination of these features raises case complexity and the likelihood of bladder injury. Pelvic organ prolapse can also cause significant anatomic distortion, and bladder injury may also occur in the setting of pelvic reconstructive surgery when a vaginal approach is utilized. Table 19.2 summarizes incidences of bladder injury with various common pelvic surgeries.

TABLE 19.2

Incidence of Bladder Injury in Common Pelvic Surgeries

SURGERY	INCIDENCE OF BLADDER INJURY	AUTHORS
Cesarean section	0.28%–0.47%	Phipps et al., 2005 Rahman et al., 2009 Salman et al., 2017
Laparoscopic total hysterectomy	0.75%	Wong et al., 2018
Laparoscopic supracervical hysterectomy	0.29%	Wong et al., 2018
Laparoscopic-assisted vaginal		Wong et al., 2018

hysterectomy		
Vaginal hysterectomy	0.51%	Teeluckdharry et al., 2015
Abdominal hysterectomy	0.58%	Teeluckdharry et al., 2015
Transvaginal tape placement	3%–9%	Sharp and Adelman, 2016
Transobturator tape placement	0.5%	Sharp and Adelman, 2016
Hernia repair (inguinal surgery)	0.08%–0.3%	Summerton et al., 2012
Laparoscopic hernia repair	1.6%	Gomez et al., 2004

Mechanisms

Laceration is the most common mechanism of intraoperative injury to the bladder, leading to the majority of intraoperative bladder-related urology consultations. More rarely, devascularization injury can occur. Table 19.3 shows bladder injury severity classification.

TABLE 19.3

Grading System for Classifying Bladder Injury

GRADE	INJURY	DESCRIPTION
1	Hematoma	Contusion, intramural hematoma
1	Laceration	Partial thickness
2	Laceration	Extraperitoneal bladder wall laceration <2 cm
3	Laceration	Extraperitoneal (>2 cm) or intraperitoneal (<2 cm) bladder wall laceration
4	Laceration	Intraperitoneal (>2 cm) bladder wall laceration
5	Laceration	Laceration extending into trigone (bladder neck or ureteral orifice)
6		Not salvegable

Data from Moore EE, Cogbill TH, Jurkovich GJ, et al. Organ injury scaling. III: Chest wall, abdominal vascular, ureter, bladder, and urethra. *J Trauma*. 1992;33(3):337–339.

It makes intuitive sense that risk for bladder injury is highest when operating within the bladder. Endoscopic surgeries, most commonly transurethral resection of bladder tumor, are the most common and also underreported. Transurethral resection of a bladder tumor or bladder biopsy are by definition intentional injuries to the bladder wall that generally heal without consequence, with or without bladder decompression with a catheter as indicated. However, extraperitoneal or intraperitoneal bladder injuries may occur that require additional intervention, either with prolonged bladder decompression in the case of most extraperitoneal injury or open repair in the case of most intraperitoneal injury. The extent of hematuria, patient requirement for postoperative anticoagulation, significance of the perforation, anticipated requirement of postoperative continuous bladder irrigation, and development of abdominal distension during endoscopy are all factors that may determine management. With the majority of these procedures performed by urologists, their management is generally within the purview of the primary surgeon rather than an intraoperative consultation, depending on the skill set of the primary surgeon.

Diagnosis/Recognition

A high index of clinical suspicion is necessary to allow recognition and prompt treatment of bladder injury. Clinical indicators include a visible laceration to the bladder, visualization of the Foley catheter, extravasation of fluid (urine) into the surgical field, and blood (and/or gas during laparoscopy) into the catheter drainage bag (Gomez et al., 2004).

If there is clinical concern for injury without an obvious defect seen, fluid (with or without dye, e.g., methylene blue) may be instilled into the bladder via the catheter to help locate the injury. When fluoroscopy is available, contrast can be injected into the bladder for evaluation. Cystoscopy can also be used to visually assess the bladder. This has become the standard of care for urethral sling surgeries and hysterectomy to ensure the absence of bladder injury.

When bladder injury is found, it is important to ensure there is no concomitant injury to the ureters and/or ureteral orifices (Summerton et al., 2012). Means of assessing the ureters for injury are described in the Ureteral Injury section later in this chapter.

Management

Bladder lacerations should be repaired in one or more layers using absorbable suture. Devascularized urothelium or bladder wall should be debrided as needed. The closure should be tested by filling the bladder intraoperatively, serving both the purpose of allowing additional suture placement as needed and to reconfirm that no other previously unrecognized injuries are present. A catheter draining the bladder should remain in place postoperatively, and an intra-abdominal drain should be left. Most series recommend 7 to 14 days of bladder drainage. As the vast majority of postoperative cystograms are negative, their use should be considered but reserved for those cases with particular concern for the integrity of repair, complex repairs, or when the concern level is elevated for fistula formation.

When an injury is suspected but not visualized, a cystotomy may be performed to facilitate identification of the area of injury (Esparaz et al., 2015). Injuries involving the trigone may be more complex to repair. Ureteral integrity must be established, and the anterior vaginal wall may be involved, increasing the likelihood of postoperative fistula formation. When in question, the ureter should be reimplanted as the downstream consequences of leaving an injured ureter unrepaired are significant (Blackwell et al., 2018). Postoperative cystography carries a role in complex repairs to ensure that there is no leak before catheter removal and that no fistula has occurred (Sharp and Adelman, 2016).

Ureteral Injury

Incidence

Iatrogenic injury is the most common cause of ureteral injury comprising 75% to 80% of all cases (Dobrowolski et al., 2002; Elliott and McAninch, 2006). Injury can occur in abdominal or pelvic surgeries and with all modalities—open, laparoscopic, robotic, and endoscopic). Ureteral injuries have also been rarely reported after spinal surgery but are not typically recognized intraoperatively (Bjurlin et al., 2009; Pillai et al., 2013). Similar in contributing factors to those for bladder injuries, the fixed space of the pelvis, complex anatomy, prior procedures, or radiation therapy can all increase risk by altering the normal anatomic position of the ureter and by making it more difficult to identify. More than 90% of ureteral injuries are to the distal one-third of the ureter (Selzman and Spirnak, 1996). In modern series, the incidence of mid- and proximal ureteral injuries has risen likely as a result of increased endoscopic procedures by urologists, and distal injuries compose about three-fourths of cases (proximal and mid-ureteral injuries each composing about 13%) (Dobrowolski et al., 2002).

Most series report gynecologic surgeries as the source for a majority (>50%) of ureteral injuries (Blackwell et al., 2018; Brandes et al., 2004; Burks and Santucci, 2014). With changing technologies and an increasing number of endoscopic urologic procedures, there are series that report endoscopy as the source of a majority of ureteral injuries (Al-Awadi et al., 2005; Romero et al., 2011). Regardless, high-grade injuries (such as avulsion) during endoscopic procedures are rare. Changing technologies with increased shift toward minimally invasive (laparoscopic and robotic) surgeries have also been thought to increase iatrogenic injury. Gynecologic surgeries remain the predominant cause with colorectal, vascular, and urologic surgeries also contributing. Table 19.4 shows a summary of incidence of ureteral injury based on surgery type.

TABLE 19.4

Incidence of Ureteral Injury by Type of Surgery

SURGERY	INCIDENCE	AUTHOR
Transvaginal hysterectomy	0%–0.04%	Carley et al., 2002; Sharp and Adelman,

		2016
Transabdominal hysterectomy	0.35%–30%	Carley et al., 2002; Esparaz et al., 2015
Colorectal surgery	0.44%–5%	Anderson P, 2015; Burks and Santucci, 2014
Ureteroscopy	0.3%–4.1%	Esparaz et al., 2015

Mechanisms

The mechanisms for injury to the ureter are highly variable and can affect the options for management. Mechanisms include laceration (partial or complete), ligation (partial or complete) with kinking or occlusion, resection, crush injury, thermal injury, abrasion, avulsion, or devascularization. The mechanism of injury generally affects the grade of injury and the management. Table 19.5 summarizes grading of ureteral injury.

TABLE 19.5

Grading System for Classifying Ureteral Injury

GRADE	INJURY	DESCRIPTION
1	Hematoma	Contusion or hematoma without devascularization
2	Laceration	<50% transection
3	Laceration	>50% transection
4	Laceration	Complete transection with ≤2 cm devascularization
5	Laceration	Complete transection with >2 cm devascularization
6		Not salvageable

From Best CD, Petrone P, Buscarini M, et al. Traumatic ureteral injuries: a single institution experience validating the American Association for the Surgery of Trauma-Organ Injury Scale grading scale. *J Urol*. 2005;173(4):1202–1205.

Diagnosis/Recognition

A majority of iatrogenic ureteral injury goes unnoticed. Only 36% of ureteral injuries are recognized at the time of initial surgery during open surgical cases (Selzman and Spirnak, 1996). Even fewer injuries (12.5%) are recognized during laparoscopic surgery (Esparaz et al., 2015). **Early recognition of ureteral injury is important as failure to do so carries significant morbidity (pain, infection, azotemia, fistula formation, and reoperation).** Data also suggest that immediate recognition and repair portends more favorable outcomes in addition to fewer additional complications (Al-Awadi et al., 2005; Blackwell et al., 2018).

A very high index of suspicion is needed to identify these injuries, particularly during laparoscopy. Some indications of injury include extravasation of fluid (urine) into the surgical field, hydroureteronephrosis, or visualization of ureteral catheters (if placed preoperatively). Although hematuria should raise the level of clinical concern for ureteral injury, the absence of hematuria does not rule out clinically significant injury (Brandes et al., 2004).

There are multiple ways to assess the ureter when there is concern for ureteral injury in the intraoperative setting. Cystoscopy with retrograde urography can be used to assess the ureter. This has been shown to be the most accurate means in diagnosing the location and degree of injury and is considered the gold standard (Brandes et al., 2004). Retrograde studies can reliably identify or rule out ureteral injury and can often obviate the need for additional surgical dissection and direct visual assessment of the ureter if the study is normal. Retrograde urography is a particularly useful means of assessment during endoscopic procedures. **For cystoscopy alone, efflux can still be seen in the setting of partial transection or ligation and so retrograde pyelography is important when clinical suspicion for injury is high** (Teeluckdharry et al., 2015). Direct endoscopic inspection with ureteroscopy or ureteral stenting/catheterization may also be used. Unobstructed passage of ureteral catheters into the renal pelvis without resistance suggests that no significant ligation or lacerations are present. However, with many open, laparoscopic, or robotic surgeries, the patient may not be positioned appropriately, prepped, or on a surgical table in which retrograde urography, stenting, or direct inspection with ureteroscopy is possible.

Intraoperative excretory urography (e.g., intravenous pyelography) can be used in such cases. An abnormal or nondiagnostic finding warrants exploration (Brandes et al., 2004). Excretory dye (e.g., indigo carmine or methylene blue) may be used as well. Direct visualization of dye within the surgical field is indicative of higher-grade injury, and further exploration and direct visualization is needed. Excretory dye can be administered not only intravenously in these settings, but may also be injected directly into the urinary tract for more prompt assessment via ureteral catheter placement and injection or direct small-bore needle injection into the renal pelvis or ureter.

Meticulous dissection and direct inspection are critical to evaluating the ureter intraoperatively when injury is suspected and retrograde urography is not available. Adequate visualization is required, and further dissection should take place as needed to ensure the integrity of the ureter. Although inspection should allow for identification of a laceration or ligation, care should be taken to inspect for signs of ureteral contusion including bruising or hematoma and signs of devascularization injury including dusky appearance and/or lack of bleeding (Brandes et al., 2004). Although an open approach has been the gold standard for direct visualization, laparoscopic and robotic evaluation and repair in these settings may be feasible depending on the skill set of the consulting urologist (Han et al., 2012; Tracey et al., 2018). The ultimate deciding factors should be the urologist's preference, comfort, and proficiency that determine the modality of direct inspection.

Management

Management of ureteral injury is dependent not only on the location and mechanism of injury, but also importantly on patient characteristics and the expertise of the consulting urologist. The goals of management should be preservation of renal function and minimizing morbidity for the patient.

AUA guidelines recommend repair of traumatic ureteral injuries at the time of exploration in stable patients (grade C), and these recommendations may be extrapolated to acute iatrogenic injuries as many of the same principles apply (Morey, 2014). As the consulting surgeon, care should be taken to avoid pitfalls. In a stable patient, time should be taken to gather as much as information as possible that may influence the next course of action. The planned operation by the primary surgeon, indication for surgery, prior medical and surgical history, and reasons for suspecting ureteral injury or mechanism of injury, if known, should all be explored. If imaging is available, it should be reviewed to assist in risk stratification and surgical planning.

For unstable patients, temporary diversion can be employed and definitive management delayed until such time that the patient is able to tolerate a definitive repair (Morey, 2014). Diversion can take place with ligation of the ureter and percutaneous nephrostomy tube placement or with ureterostomy (Brandes et al., 2004). Temporary diversion can also be employed if the consulting surgeon lacks the skill set or expertise to complete the necessary interventions. Effort should be made to elicit additional help as necessary to prevent multiple procedures for the patient. But the primary rule of medicine remains—first do no harm.

Principles of Repair

The principles of ureteral repair remain the same regardless of the location of injury. It is important to debride devascularized tissue as needed. The lumen of the ureter should be maintained by creating a spatulated and tension-free mucosa-to-mucosa anastomosis with absorbable sutures. The closure should be watertight, and an indwelling ureteral stent should be placed to maintain ureteral patency and encourage urine flow across and not out through the area of reanastamosis. An external drain should be left in place postoperatively (Serafetinides et al., 2015). As possible, interposing omentum or peritonealization can aid in anastomosis healing and prevent fistualization.

Grade 1 and 2 Injuries

Low-grade injuries can occur via ligation, cold laceration, crush injuries, or minor thermal injuries. With ligation, the offending clip or suture should first be removed. Ligation injuries are the most common ureteral injury encountered in gynecologic surgery (Brandes et al., 2004). Grade 1 and 2 injuries should be managed with placement of a ureteral stent or nephrostomy tube (Summerton et al., 2012). Ureteral stenting is preferred over placement of a nephrostomy tube because there is a decreased risk for ureteral stricture formation (Brandes et al., 2004). This includes stenting in cases of ureteral contusion or small lacerations when clinically indicated.

Generally stents are left in place for 2 to 6 weeks (Gild et al., 2018). Evidence is lacking as to how these patients should be followed or reevaluated after their injury. It is prudent to obtain upper tract imaging (ultrasonography or CT) after stent removal to ensure the lack of stricture formation or obstruction. Renal scan may also be indicated to further evaluate for obstruction if other imaging is indeterminate.

Grade 3 to 5 Distal Ureteral Injuries

High-grade distal ureteral injuries should be managed with ureteroneocystotomy as the vascularity of a ureter-ureter anastomosis in this location is often compromised by the original injury and jeopardizes the chances for successful primary repair (Serafetinides et al., 2015). Although either nonrefluxing or refluxing reimplantation may be used, there is no clear advantage to a nonrefluxing anastomosis in an adult patient. The refluxing approach is generally preferred in the acute setting of intraoperative consultation because of its efficiency and lower risk for obstruction at the anastomosis (Baston et al., 2014; Burks and Santucci, 2014).

When direct reimplantation is not viable because of insufficient ureteral length, a psoas hitch can be used. The ipsilateral superior portion of the bladder's detrusor muscle is sutured to the ipsilateral psoas tendon to gain length and decrease tension on the anastomosis. Developing the space of Retzius and ligation of the contralateral bladder pedicle can allow for further mobilization of the bladder. When either of these maneuvers are insufficient, a tubularized bladder flap (Boari flap) or bladder advancement flap can be used to gain additional length. The technical aspects of these surgical procedures are reviewed in Chapters 42 and 53.

After reimplantation, a urinary catheter is left in the bladder for decompression while the bladder and anastomosis heal. A perivesical drain is left adjacent to the anastomosis, and most series report catheter use for 1 to 2 weeks. Cystography, as with repair of bladder injury, should be used selectively based on the complexity and concern regarding the integrity of the repair. The internal indwelling stent remains in place after the catheter is removed, usually for a total of 4 to 6 weeks postoperatively. As outlined earlier, the ureter should be assessed with imaging after all drains have been removed to confirm the absence of stricture (Sharp and Adelman, 2016).

Grade 3 to 5 Mid- and Proximal Ureteral Injuries

For higher-grade injuries above the level of the iliacs, primary repair over a ureteral stent should take place as possible (grade C) (Morey, 2014). Ureteroureterostomies are best for small ligation injuries and crush injuries when ureteral stenting alone is not possible (Brandes et al., 2004).

Grade 5 Injury

When complex repairs are needed, there should be strong consideration to temporize the patient and defer repair. Complex proximal ureteral injury repairs requiring reconstruction, such as ureterocalicostomy, transureterostotomy, ileal ureter interposition, or autotransplantation, may have significant risks and long-term effects to a patient's health and quality of life. Newer data on the use of appendiceal on lay grafts or buccal mucosal grafts to repair ureteral stricture disease provide additional options to consider with potentially less morbidity (Duty et al., 2015; Zhao et al., 2017). However, their use in the setting of an intraoperative consultation for ureteral injury has not been explored. Not only do these procedures require significant surgical expertise, but decisions to utilize any one of these approaches should enlist shared decision making between the patient and surgeon. It is challenging, and arguably impossible, to hold discussions with family members such that an informed decision can be made in the setting of unanticipated ureteral injury requiring potentially life-impacting, complex repair. Temporizing measures are strongly preferred here as best management practice.

Ureteroscopic Avulsion Injury

Serious ureteroscopic injury with avulsion is rare, with incidence reported as 0.06% to 0.45% (D'Addessi and Bassi, 2011). The proximal to mid-ureter is the region most prone to avulsion, which most commonly occurs with application of excessive force to a basketed stone at a site of impaction or ureteral narrowing. The primary goal in immediate management of avulsion injuries is to reestablish continuity. This can be accomplished in the same manner as other grade 4 laceration injuries. Immediate repair with ureteroureterostomy should be performed (assuming mid- or proximal ureteral location) (Brandes et al., 2004). Other management options include reimplantation (for distal avulsion) and ureterocalycostomy (for proximal injuries).

Ureteral Catheters

Depending on the culture at a particular hospital or institution, intraoperative consultations for ureteral catheterization before other colorectal or gynecologic surgery may be common or relatively rare. Ureteral catheters are requested most commonly in cases with anticipated anatomic distortion, making ureteral identification more challenging. Acute diverticulitis requiring surgery, large pelvic masses, prior radiation history, or prior surgery can all prompt consultation for ureteral catheter placement. Although there is perceived benefit by some that catheters help surgeons to locate the ureters, it has been demonstrated that prophylactic catheters do not decrease the risk for ureteral injury (Chou et al., 2009). However, catheters may help in the identification of ureteral injury when present. Ureteral catheters also carry risk that should not be underestimated or ignored. Iatrogenic injury may occur related to ureteral catheterization (Bothwell et al., 1994). Ureteral catheters also independently increase both the cost of hospitalization and the risk for acute kidney injury (AKI) in the postoperative setting, with 32.6% of catheterized patients versus 10.5% of noncatheterized patients developing AKI (Hassinger et al., 2018). In the same study, bilateral catheters also produced a higher incidence of AKI relative to unilateral catheter placement, suggesting catheter-related ureteral edema may be a likely etiology of AKI.

Because catheter placement is almost always an anticipated request, it is recommended that patients be counseled in advance regarding the risks and benefits of such a procedure by a urologist. In addition, the primary surgeon should regard it as their ethical responsibility to the patient both to reserve intraoperative consultations for unanticipated findings and to allow patients to be counseled as appropriate.

Renal Injury

Incidence

A majority of renal injury is traumatic, not iatrogenic, and thus intraoperative consultation for renal injury is far less common than that for other genitourinary organs. Although iatrogenic renal injury is rare, it can carry significant morbidity.

Mechanisms

Because a majority of renal injury is caused by trauma, the primary mechanisms for injury are blunt and penetrating. For iatrogenic injuries, hemorrhage is the most common issue resulting from renal vascular or parenchymal injuries. These can occur with many urologic procedures (e.g., percutaneous nephrolithotomy [PCNL], renal biopsy, enopyelotomy) but also with open abdominal or endovascular surgery (Esparaz et al., 2015). PCNL has become the most common cause of renovascular injury occurring in 0.9% to 3% of cases (Esparaz et al., 2015).

Diagnosis/Recognition

With a majority of iatrogenic cases occurring during PCNL, bleeding is most often recognized postoperatively as a result of gross hematuria, acute blood loss anemia, flank pain/flank hematoma, and hemodynamic stability. Most of these cases can be managed either conservatively or with interventional radiology and selective embolization. For acute renal bleeding, it is rare that urologic consultation is sought because of the acuity. Please refer to the subsection on renal trauma in Chapter 133 for details about this surgical approach.

Management

Management of renal trauma has trended more and more toward conservative approaches, even for high-grade injuries. Current AUA guidelines recommend immediate intervention (surgery or angioembolization) only in hemodynamically unstable patients or patients only transiently responsive to resuscitation [grade

B] (American Urological Association, 2017). For iatrogenic injury, most are minor and require supportive care and a conservative approach (Esparaz et al., 2015). In cases of significant bleeding during PCNL, this is usually venous in nature. Conservative measurements with catheter tamponade, clamping of the nephrostomy tube, mannitol administration, and placement of a larger nephrostomy tube are generally effective, and patients do not require exploration. Even for arterial bleeding, open exploration is generally not indicated, and interventional radiology selective angioembolization can be used to control hemorrhage. Angioembolization has been shown to decrease renal parenchymal loss and patient morbidity when compared with open exploration (involving partial or total nephrectomy) (Esparaz et al., 2015).

Key Points

- When bladder injury is found, it is important to ensure that there is no concomitant injury to the ureters or ureteral orifices.
- When a bladder injury is suspected but not visualized, a cystotomy may be performed to facilitate identification of the area of injury.
- Early recognition of ureteral injury is important as failure to do so carries significant morbidity.
- If ureteral injury is suspected but not visualized, imaging and/or endoscopic assessments should be performed to confirm the presence or absence of injury.
- Consultation for ureteral catheter placement should be reserved for the preoperative setting and for appropriately selected cases.

Placental Cases

Placental abnormalities carry a unique risk for obstetric surgeries. Abnormalities of placental attachment to the uterine wall are subclassified based on their depth of attachment. Placenta accreta, increta, and percreta classifications are made, respectively, with increasing invasiveness and complexity, though the term *placenta accreta* is often used to encompass the entire spectrum of disease (Silver and Barbour, 2015). These abnormalities carry significant risk for hemorrhage and morbidity. The incidence of accreta cases is climbing, likely related to increase in cesarean delivery, a known risk factor for development. Most cases of placenta accreta occur in patients with placenta previa (where the placenta is positioned low within the uterus and partially or completely covers the cervix). As such, accreta should be suspected in cases of placenta previa and should be evaluated accordingly.

Antenatal diagnosis of placenta accreta is important to management, allowing for appropriate operative planning. The most common means of assessment of the placenta is via ultrasonography. A high clinical suspicion is needed as data on sensitivity of ultrasonography to diagnose accreta is conflicting (Silver and Barbour, 2015). Magnetic resonance imaging (MRI) is often employed to try and aid in antenatal diagnosis, and there are mixed data as to whether it improves the accuracy of ultrasonography alone. Most studies on the sensitivity of imaging in diagnosing accreta are subject to bias (e.g., centers of excellence, known high-risk patients). At this point, it does not appear that MRI clearly changes management or improves outcomes overall, but MRI may have advantages specifically for placenta percreta in assessing the degree of invasion, which is important for presurgical planning (Jauniaux and Bhide, 2017; Silver and Barbour, 2015; Thiravit et al., 2017).

Placenta accreta cases are often managed with early cesarean delivery (34 to 35 weeks) to prevent emergency surgery at the time of labor. Often, hysterectomy is performed at the time to prevent dissection of the placenta. Controlled cesarean hysterectomy is associated with decreased morbidity as compared with cases in which removal of the placenta is attempted with the uterus left in place (Eller et al., 2009). Other management options include internal iliac artery embolization and postoperative use of methotrexate to shrink residual placental tissue. Suggested criteria for management of these complicated patients include involvement of a multidisciplinary team that involves urology. The reason for this is that placenta percreta cases can extend so deeply as to involve local organs such as the bladder and ureter. The most common site of placental invasion is the posterior aspect of the bladder (Silver and Barbour, 2015).

The urologist may have multiple roles in caring for these patients, both preoperatively and intraoperatively. Antenatally, patients may be evaluated for suspected percreta involving the bladder wall. Retrospective review of placenta percreta cases involving the bladder has shown bleeding to be the most common presenting complaint, with vaginal bleeding initially occurring in almost one-half of patients (Washecka and Behling, 2002). Only an approximate one-third of patients in this series had hematuria (gross or microscopic) (Washecka and Behling, 2002). Cystoscopy does not appear to be sensitive for determining all cases of bladder wall involvement as mucosa may not be involved or altered, even with extensive muscularis involvement. However, cystoscopy remains warranted for evaluation and preoperative planning (Konijeti et al., 2009; Washecka and Behling, 2002). If percreta is suspected and there are cystoscopic abnormalities, it is important to forego biopsy in these cases as it carries a risk for gross exsanguinating hematuria (Washecka and Behling, 2002).

Intraoperatively, urologic consultation may be called for in cases in which placenta accreta was unknown or in cases in which the patient did not seek prenatal care. Cystotomies may occur intentionally or incidentally during dissection of the uterus. Bladder repair should take place as usual, with complete resection of placental tissue and closure in two layers. Omental interposition should be considered to avoid development of a fistula as indicated. The bladder is left to dependent drainage with a urethral catheter, and a pelvic drain may be left in place to evaluate for urine leak postoperatively. Cystography may be considered postoperatively before catheter removal, depending on the quality of the cystorrhaphy and surgeon preference.

There are cases in which subtotal hysterectomy is performed with invasive uterine tissue left in place as removal would result in significant anatomic and functional impact to the patient. Examples include defunctionalized bladder capacity from resection or requirement for ileal ureter creation in cases of significant ureteral involvement. Postoperatively, methotrexate has been employed to shrink residual placental tissue and prevent additional surgeries and additional blood loss (Karras et al., 2015). However, significant hemorrhagic shock has occurred in patients with retained placenta, and the standard of care remains as removal of all placental products (Washecka and Behling, 2002).

Ureteral injury and involvement can occur in these cases up to 7% of the time (Eller et al., 2009). There are some data to suggest that placement of ureteral catheters may decrease the risk for ureteral injury and early morbidity in cases of placental abnormality (Eller et al., 2009). This holds true for both nonemergent and emergent cases. If ureteral injury occurs or is suspected, just as outlined earlier in this chapter, it is the responsibility of the consulting urologist to do what he or she feels is best for the patient *and* within his or her skill set.

Consults From Urology Colleagues

Just as with any intraoperative consultation, the call for help from colleagues within the same discipline may occur. The surgical skill sets of the primary urologist and consulting urologist may have significant overlap, and generally this implies a higher degree of case complexity or challenging decisions to be made necessitating the call. It may also be the case that the urologist on call does not have the surgical skill set necessary to address an intraoperative consult from a primary surgeon within another discipline. Sometimes the call is made by the primary urologist simply to reaffirm the decision being considered before proceeding with the surgery. Whatever the reason, intraoperative consults from colleagues within urology should be considered as a particularly high honor and a sign of respect.

Embryology of the Genitourinary Tract

Laurence S. Baskin MD, Gerald Cunha PhD

The human urogenital system can be divided into the urinary and reproductive systems. These systems are closely interrelated, especially early in development, which begins in the first trimester and is mostly complete by the end of the second trimester. The Carnegie collection of embryos depicts human development from the time of fertilization to the indifferent stage at approximately 8 to 9 weeks' gestation (Fig. 20.1; Mall and Meyer, 1921; Smith, 2016). **Subsequently, under the influence of androgens, differentiation of the male and female urogenital structures becomes apparent** (Blaschko et al., 2012; Fig. 20.2). In this chapter, we review the development of the human urogenital tract by organ system: external genitalia, prostate, gonads, uterus, vagina, bladder, ureters, and kidneys. Understanding normal development is essential for understanding abnormal development or urologic congenital anomalies and is the first step in planning treatment and surgical reconstruction if indicated.

FIG. 20.2 Gross ontogeny of the human fetal pelvis from 9 weeks' gestation (end of indifferent stage) to 16 weeks' gestation. Note the divergent development after 9 weeks' gestation, especially with respect to orientation of the external genitalia with the penis clearly visible at an approximately 90-degree angle from the body and the clitoris recessed close to the body wall.

Development of the External Genitalia

At 8 to 9 weeks' gestation, the external genitalia consist of an indifferent genital tubercle (Fig. 20.3). Sexual differentiation of the external genitalia is dependent on prior differentiation of the gonads. **The process of normal gonadal sexual differentiation is determined by the SRY region on the short arm of the Y chromosome** (Larney et al., 2014; Ohnesorg et al., 2014). The gene products of the SRY genetic cascade direct testicular development (Windley and Wilhelm, 2015). Additional genetic information required for development of male and female accessory sexual structures is located on the X chromosome and on the autosomes (Blaschko et al., 2012).

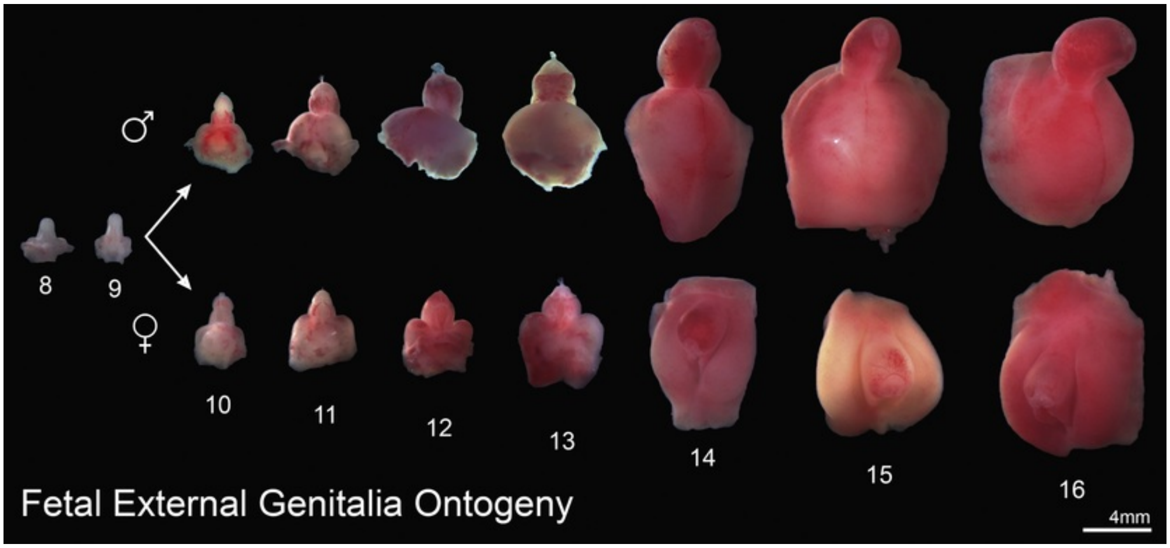

FIG. 20.3 Representative examples of human male *(top row)* and female *(bottom row)* external genitalia (8 to 16 weeks' gestation). Note the morphologic differences between the male and female genitalia after the indifferent stage (8 to 9 weeks' gestation), with lack of urethral fusion in the female specimens.

At approximately 9 weeks' gestation, the Leydig cells appear in the testis and begin to secrete testosterone (Blaschko et al., 2012; Dufau, 1988). Testosterone or the more potent androgen, dihydrotestosterone (DHT), masculinize the genital tubercle, **Wolffian duct (WD), and urogenital sinus (UGS).** Metabolic conversion of testosterone to DHT is mediated by type 2 5α-reductase, is expressed within the UGS and the genital tubercle, and is required for normal penile and prostatic development (Blaschko et al., 2012; Wilson et al., 1993; Wilson, 2001).

Masculinization of the external genitalia takes place under the influence of androgens. One of the first signs of masculinization is an increase in the distance between the anus and the genital structures (known as *anogenital distance*), followed by elongation of the genital tubercle and formation of a urethral plate (Fig. 20.4). The male genital tubercle, future penis, and clitoris contain tissue derived from all three germ layers. Ectoderm gives rise to the skin of the phallus. Mesoderm gives rise to the corporal bodies/erectile tissue. Endoderm gives rise to the urethra (see Fig. 20.4) and vestibular plate. The urethral plate (derived from endoderm) extends from the “pelvic urethra” into the future glans penis, terminating just before the distal tip of the future glans (Fig. 20.5). The urethral plate canalizes from proximal to distal to form a wide, diamond-shaped urethral groove within the penile shaft (opening zipper; Figs. 20.6 and 20.7). The canalization process is seen in the histologic sections in Fig. 20.5. Cellular proliferation (documented by the expression of Ki67) is abundant in the canalizing urethral plate (see Fig. 20.5), and apoptosis was not detected (based on the lack of expression of caspase 3; see Fig. 20.5C). The penile urethra forms as a result of complex fusion of the medial edges of the urethral folds (see Figs. 20.6 and 20.7). As development progresses, the epithelial edges of the urethral groove begin to fuse to form the midline penile raphe (closing zipper). By 11 to 12 weeks’ gestation, the coronal sulcus is evident separating the penile glans from the shaft. By 16 weeks, the urethral folds have completely fused in the ventral midline of the penile shaft (see Fig. 20.3). The normal ventral penile curvature, or chordee, that occurs during development resolves by the 20th week.

E-cadherin is expressed at epithelial surfaces in development, Cytokeratin 6 is expressed in the urethral plate and epidermis, and Cytokeratin 7 is expressed in urothelium.

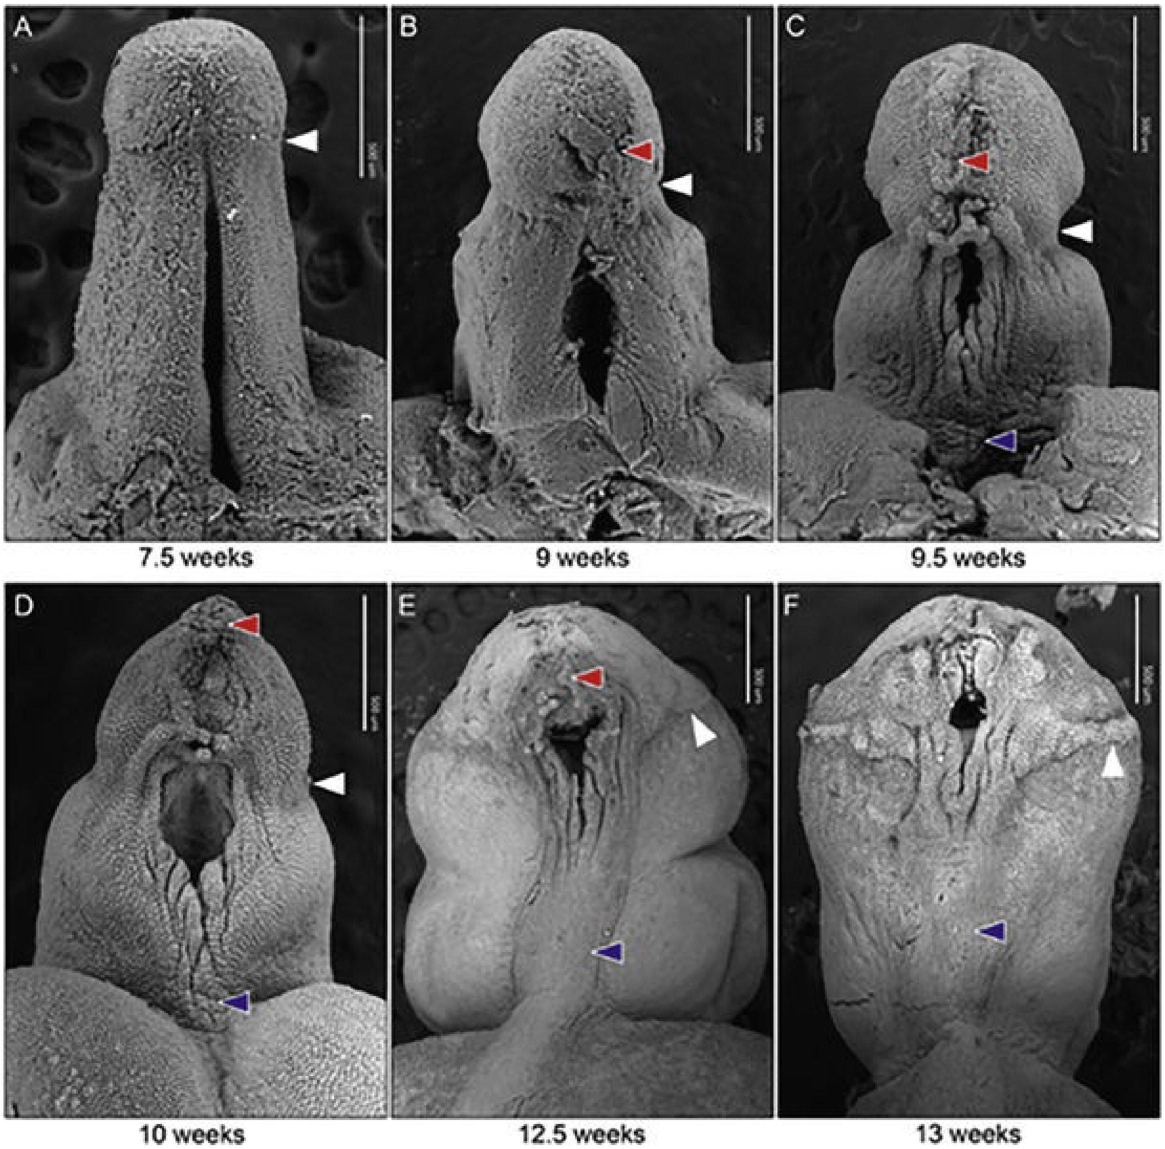

FIG. 20.7 (A to F) Scanning electron microscopy ontogeny of the developing human fetal penis from 7.5 to 13 weeks' gestation in ventral view. *White arrowheads* indicate the junction of the penile shaft to glans, *red arrowheads* indicate the distal epithelial tag, and *blue arrowheads* indicate the median penile raphe. (From Shen J, Overland M, Sinclair A, et al. Complex epithelial remodeling underlie the fusion event in early fetal development of the human penile urethra. *Differentiation*. 92(4);2016:169–182.)

The glanular urethra forms via a mechanism entirely different from urethral fold fusion, which occurs within the penile shaft (Liu et al., 2018). **Current evidence supports the view that the glanular urethra forms from UGS epithelium** (Kurzrock et al., 1999). The glanular urethra forms as a result of direct canalization of the urethra plate with epithelial remodeling within the glans (Baskin et al., 2018; Liu et al., 2018). By 18 weeks' gestation, penile and urethral development is essentially complete (Fig. 20.8).

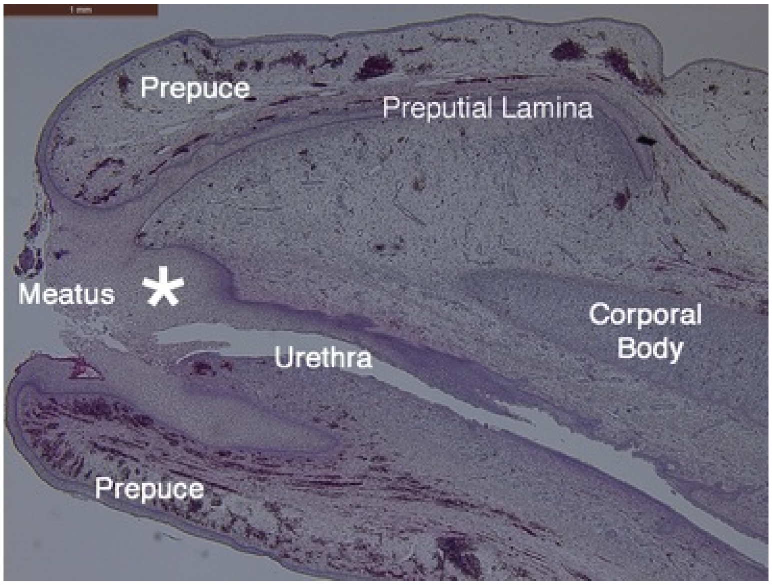

FIG. 20.8 Sagittal section of an 18-week human fetal penis. Note the remodeling of the distal aspect of the urethra. The glans, prepuce, corporal cavernosa, urethra, and meatus are labeled.

Anatomic and immunohistochemical studies suggest that epithelium of the entire urethra is derived from endoderm of the UGS (Kurzrock et al., 1999). The entire male urethra, including the majority of the glanular urethra, is formed from the endodermal urethral plate within the genital tubercle as a result of urethral fold fusion within the shaft and direct canalization of the urethral plate within the glans. This is in contrast with the outdated ectodermal extrusion theory of Glenister, which hypothesized that the glanular urethra formed by skin (ectodermal intrusion) growing into the glans and meeting the endodermally derived urethra (Glenister, 1954).

The future prepuce forms at the same time as the glanular urethra and is dependent on normal urethral development as described earlier. At about 8 weeks' gestation, low preputial folds appear on both sides of the penile shaft, which join dorsally to form a flat preputial ridge at the proximal edge of the corona. The preputial ridge initially does not entirely encircle the glans because it is blocked ventrally by incomplete development of the glanular urethra. With further development, the bilateral preputial folds (ventrolateral edges of the preputial ridge) extend distally to eventually cover most of the glans. At the same time, the bilateral preputial folds (foreskin) grow ventrally and fuse together in the ventral midline. During this process of distal and ventral growth of the prepuce, the epithelial preputial lamina is laid down, which separates the mesenchymal core of the glans from the mesenchyme of the prepuce, whose outer surface is covered with epidermis (see Fig. 20.3). Postnatally, the preputial lamina delaminates creating the preputial space, thus allowing retraction of the prepuce. **Clearly the development of the prepuce is linked to development of the urethra, because in hypospadias, preputial tissue is absent ventrally and excessive dorsally** (classic dorsal hooded foreskin; Baskin, 2017).

The origin of the nerve supply of the penis may be traced to week 5 of gestation, when neural crest cells differentiate into the peripheral and autonomic nervous systems. The somatic innervation of the penis comes principally from spinal nerves S2 to S4 by way of the pudendal nerve (Lue et al., 1984). After passing under the sacrospinous ligament and over the sacrotuberous ligament and through Alcock's canal (pudendal canal), the pudendal nerve passes through the transverse perineal muscle to course onto the dorsum of the penis as the dorsal nerve of the penis (Fig. 20.9; Breza et al., 1989). The autonomic innervation of the penis arises from the vesical and prostatic plexi, which are composed of sympathetic nerves from L1 and L2, and parasympathetic nerves from S2 to S4. The bilateral cavernous nerves leaves the pelvis between the transverse perineal muscles and the membranous urethra before passing beneath the arch of the pubis to supply each corpus cavernosum (Paick et al., 1993).

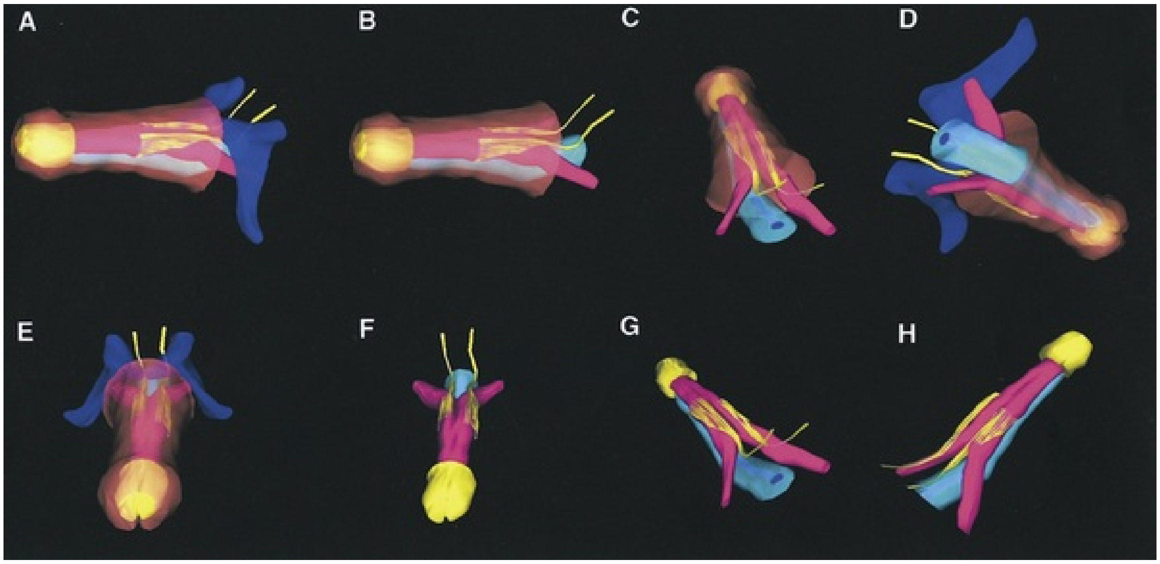

FIG. 20.9 (A to H) Multiple views of three-dimensional reconstruction of

human fetal penis dorsal nerve neuroanatomy at 17.5 weeks' gestation with respective layers removed for selective visualization. *Blue areas* represent pubic arch. *Yellow areas* represent nerves and glans. *Light blue areas* represent urethra. *Pink areas* represent corporeal bodies. *Brown areas* represent penile skin.

The dorsal penile nerve bundles exist not only in the 11 and 1 o'clock positions, but extend around the tunica to the junction of the corpus spongiosum and corpora cavernosa. Note the nerve-free zone at the 12 o'clock position (see Fig. 20.9; Baskin et al., 1998).

Clinical Correlation: Hypospadias

Hypospadias occurs in approximately 1 : 250 newborn males (Baskin, 2017). Hypospadias can be defined as (1) ectopic location of the urethral meatus, (2) incomplete development of the prepuce (dorsal hooded foreskin), and (3) ventral skin deficiency/penile curvature. **The most common location of the ectopic urethral meatus is at the junction of the penile shaft and glans penis (Baskin, 2017). This is consistent with the different mechanisms of urethral formation between the shaft of the penis and the glans (urethral fold fusion in the shaft and direct canalization of the urethral plate with the glans).** Fig. 20.10 shows two human fetal specimens, one with glanular hypospadias with the classic ectopic meatus and dorsal hooded foreskin and the other with persistent penile curvature secondary to penile scrotal webbing. The anatomy of the hypospadiac penis is exactly like a normal penis except for abnormalities in the development of the urethra and overlying skin and a ventrally deficient prepuce (Baskin et al., 1998). The abortive elements of the urethra and urethral spongiosum such as epithelium, connective tissue, smooth muscle, and blood vessels can be found in the adjacent tissue consistent with the hypospadias being an arrest in development and not a deformation anomaly (Baskin et al., 1998).

FIG. 20.10 A 24-week human fetal penis with classic distal hypospadias (A) and a 23-week human fetal specimen with chordee without hypospadias and penile webbing (B).

In the overwhelming majority of cases, the etiology of hypospadias remains unknown. A reasonable hypothesis is that hypospadias is caused by genetic susceptibility and maternal exposure to endocrine disruptors (Baskin et al., 2001). Rarely, a known genetic defect is present to explain the hypospadias. For example, a defect in the enzyme 5α-reductase type 2 (which converts testosterone to DHT) leads to severe hypospadias. 5α-reductase type 2 is expressed at the site of urethral fold fusion along the penile shaft and appears necessary for normal urethral development (Kim et al., 2002). Severe hypospadias is a consistent finding in patients without the 5α-reductase enzyme who lack the ability to properly fuse the edges of the urethral groove (see Fig. 20.13).

Clinical Correlation: Correction of Penile Curvature

Anatomic studies of penile innervation have allowed for strategic design of penile straightening procedures for ventral curvature associated with hypospadias and congenital penile curvature without hypospadias (Baskin et al., 1996, 1998, 2000). Along the penile shaft, the nerves course along the tunica albuginea and extend ventrally to completely surround the cavernous bodies up to the ventral junction with the spongiosum. From the glans to the crural bodies, where the bilateral corporal bodies (crura) separate to attach to the ventral pubic rami, the nerves are grouped into tight bundles at the 11 and 1 o'clock positions. **The 12 o'clock position is a nerve-free zone amendable to placement of**

dorsal plication sutures in mild to moderate degrees of curvature (Fig. 20.11). Also, the 12 o'clock position is where the tunica albuginea is thickest, facilitating anchoring of the plication suture (Baskin et al., 1998).

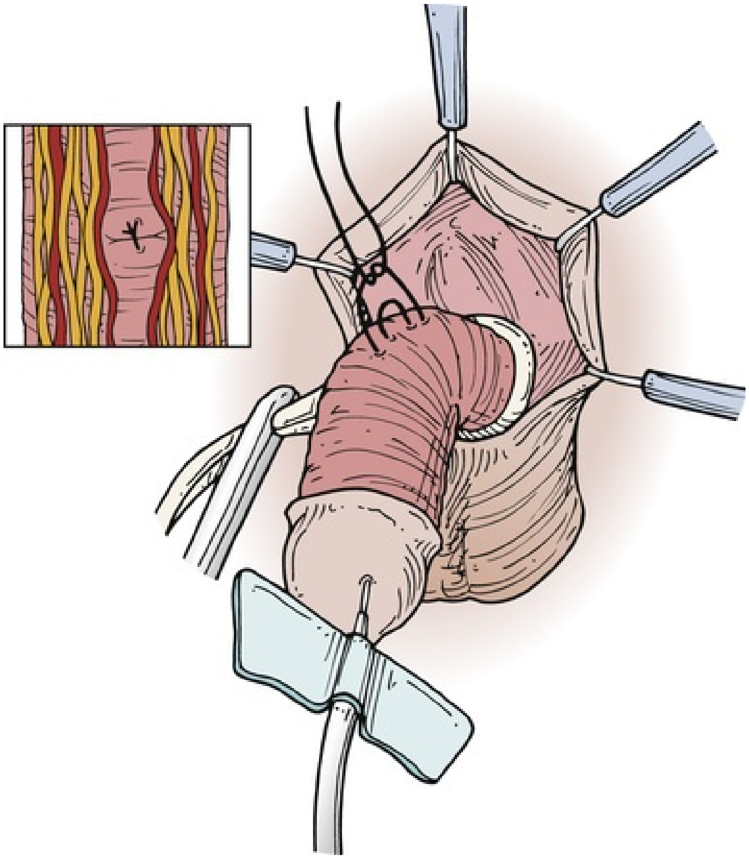

FIG. 20.11 Schematic of penile straightening technique using plication sutures at the 12 o'clock position, where there is a paucity of nerves, thereby avoiding nerve injury.

Clinical Correlation: Duplicated Urethra

Duplication anomalies of the urethra are extremely rare with both hypospadiac and epispadiac variations (Coleman et al., 2010). These are best explained embryologically by splitting of the urethral plate at the bladder to form complete duplication or splitting along the shaft of the genital tubercle to form a Y duplication. Sonic hedgehog appears to be an important genetic pathway controlling this process (Seifert et al., 2009).

Development of the Female External Genitalia

The clitoris forms in an analogous fashion to the penis except for lack of formation of the urethra (Overland et al., 2016; see Figs. 20.3 and 20.12). As in males, a urethral plate (properly called the *vestibular plate* in females) undergoes canalization to form a wide diamond-shaped vestibular groove (opening zipper, homologous to the urethral groove of males). Because formation of the vestibular groove and its subsequent canalization occurs in females (and in males), this process is androgen independent (Shen et al., 2016). **In contrast with penile formation, fusion of the urethral groove (closing zipper) does not take place, resulting in an open vestibular groove** (Overland et al., 2016; Figs. 20.12 and 20.13). Similar to the glans penis, the glans clitoris forms a cap on top of the distal end of the narrowed bilateral corporal (clitoral) bodies. Fusion of these clitoral bodies is manifest as a midline septum starting on the ventral aspect and extending about halfway into the glans. Large bundles of nerves course along the clitoral bodies with the highest density dorsally (Fig. 20.14) in a fashion analogous to the penis (Baskin et al., 1999). No nerves are noted at the 12 o'clock position, but nerves extend ventrolaterally completely around the tunica similar to that seen in the fetal penis. Like in the male, innervation of the glans clitoris occurs via multiple perforating branches that enter at the dorsal junction of the corporal body and the glans. **The lowest density of nerves in the glans is on the ventral aspect in juxtaposition to the glans septum** (Baskin et al., 1999).

Anatomical studies of the human clitoris. *J Urol.* 162(3 Pt 2);1999:1015–1020.)

Clinical Correlation: Congenital Adrenal Hyperplasia

Patients with congenital adrenal hyperplasia, an autosomal recessive disorder characterized by impaired cortisol synthesis, undergo varying degrees of virilization leading to genital atypia at birth (Auchus et al., 2010). These patients can be confused with patients with hypospadias (albeit with bilateral nonpalpable testis). Unlike normal female development, the vestibular groove undergoes varying degrees of closure forming a clitoral shaft urethra that is anatomically indistinguishable from a normal male urethra (Baskin, 2017). In the most severe cases, the clitoris looks exactly like a penis with a normal terminal urethral meatus, glans, and foreskin (Baskin, 2017). The only feature that distinguishes the male from the female is lack of palpable gonads (testes) and excess pigmentation.

Key Points: External Genitalia

- Androgens differentiate the ambisexual human genital tubercle at 7 to 8 weeks' gestation into the penis.
- The penile urethra is formed by an opening zipper (canalization of the urethral plate) followed by fusion of the urethral folds (closing zipper).
- The epithelium of the entire male urethra is of urogenital sinus origin.
- The clitoris forms in an analogous fashion to the penis except for lack of formation of the urethra within the clitoris.
- Anatomy of the hypospadiac penis is exactly like a normal penis except for abnormalities in development of the urethra, surrounding spongiosum, overlying skin, and a ventrally deficient prepuce.
- A nerve-free zone is present at the 12 o'clock position on the penile and clitoral tunica that is amendable to placement of dorsal plication sutures in mild to moderate degrees of curvature and other surgical procedures.

Development of the Human Prostate

The human prostate and seminal vesicles develop at the base of the bladder at 10 to 12 weeks' gestation (Fig. 20.15). Information on development of the human prostate is based on sparse literature on human fetal prostate coupled with extensive literature on prostatic development in laboratory animals in which detailed endocrinologic and mechanistic studies are possible. For example, the importance of androgens in prostatic development was originally determined through animal studies carried out by Alfred Jost (Jost, 1953) and Dorothy Price (Price and Ortiz, 1965) and then subsequently confirmed in humans (Wilson et al., 1981). Accordingly, in this review the contribution of animal studies to our understanding of human prostatic development will be noted.

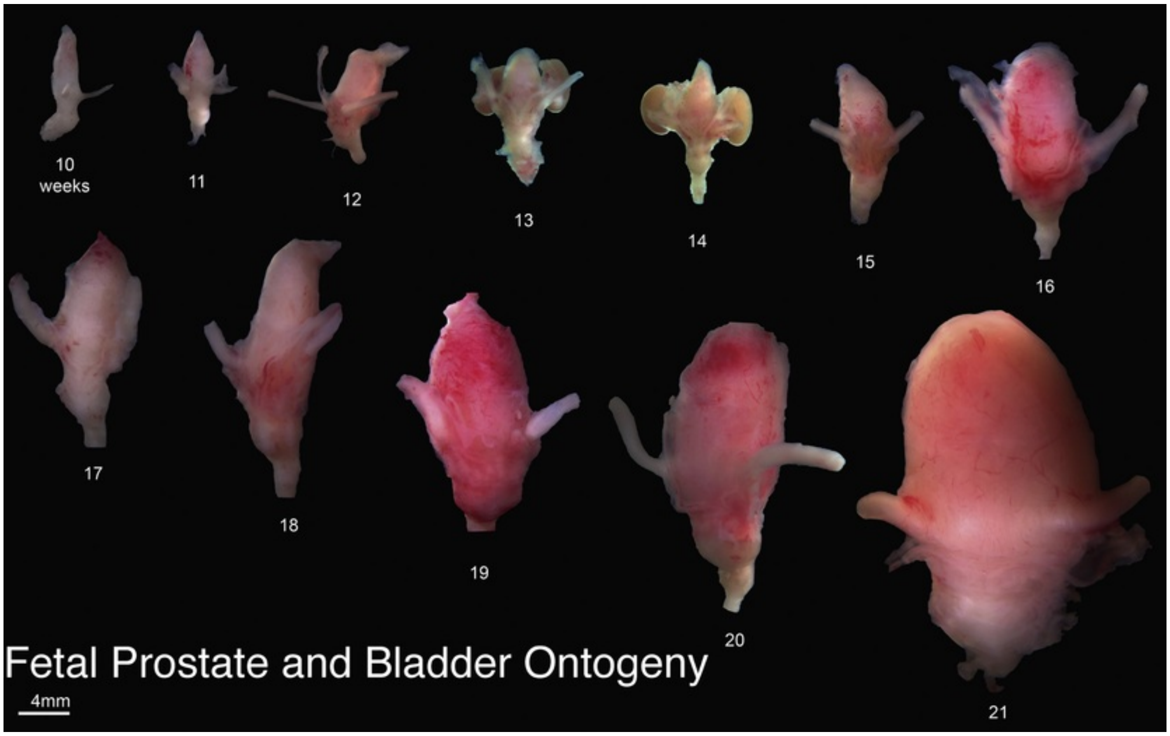

FIG. 20.15 Whole-mount photographs of human fetal bladder and prostate (10 to 21 weeks' gestation). Note the presence of the vas deferens medial to the ureters on the posterior aspect of the majority of specimens. The fetal testes and epididymis can be seen in the 13- and 14-week specimens. The fetal prostate is seen as a bulge of tissue just below the insertion of ureters and increases in size over time.

Human and mouse prostatic development can be subdivided into the following stages: (1) prebud UGS, (2) emergence of solid epithelial buds from urogenital sinus epithelium (UGE), (3) bud elongation and branching, (4) canalization of the solid epithelial “ducts,” (5) differentiation of luminal and basal epithelial cells, and (6) secretory cytodifferentiation. The human and mouse prostate develop below the urinary bladder (Fig. 20.16) from FOXA1-positive UGE. FOXA1 is a marker of the endodermal lineage (Besnard et al., 2004; Diez-Roux et al., 2011; Robboy et al., 2017). A unique feature of human prostatic development is formation of the verumontanum, a hillock elongated craniocaudally on the dorsal wall of the UGS (Fig. 20.17). The mesonephric (Wolffian) ducts and the fused Müllerian ducts (MDs; prostatic utricle) join the UGE on the apex of the verumontanum. **Thus, the verumontanum represents an interface between the mesodermal epithelia of the WDs and the prostatic utricle with endodermal UGE** (see Fig. 20.17).

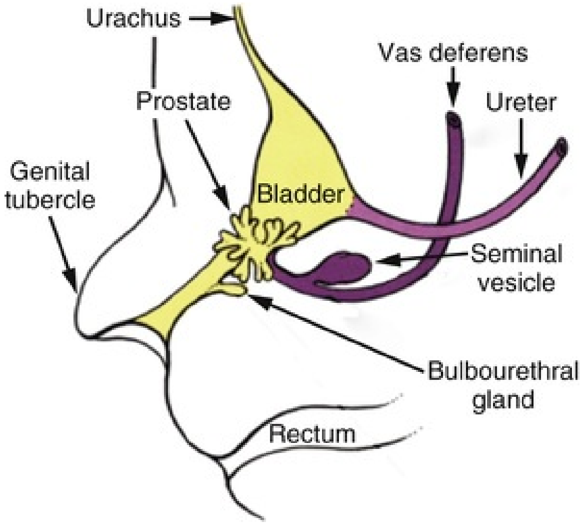

FIG. 20.16 Diagram of developing male urogenital organs. The bladder, urachus, prostate, urethra, and bulbourethral glands are derived from endodermal urogenital sinus epithelium *(yellow).* The ureter, vas deferens, and seminal vesicle are derived from the mesodermal mesonephric (Wolffian) ducts *(purple).* (Modified from Shen J, Cunha G, Sinclair A, et al. (2018). Macroscopic whole-mounts of the developing human fetal urogenital-genital tract: indifferent stage to male and female differentiation. *Differentiation*. pii: S0301-4681(18)30098-7. [Epub ahead of print].)

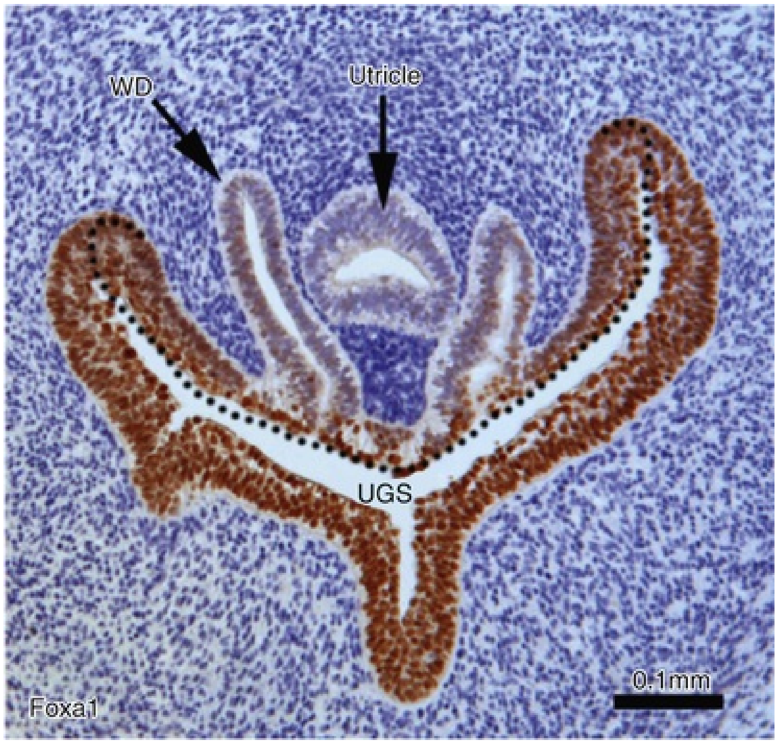

FIG. 20.17 Section of a prebud 9-week human fetal urogenital sinus *(UGS)* in the region of the verumontanum, a dorsal hillock projecting into the UGS *(dotted line).* The Wolffian ducts *(WDs)* flank the Müllerian-derived prostatic utricle, and both open into the UGS at/near the apex of the verumontanum. The section is immunostained for FOXA1, an endodermal marker.

The initial event in prostatic development is outgrowth of solid epithelial buds from the UGE into the surrounding mesenchyme during weeks 9 to 10. Because of the inherent difficulty of estimating specimen age, various investigators have reported initiation of human prostatic bud formation over a range of ages: 9.5 weeks (Dauge et al., 1986) to 10 weeks (Kellokumpu-Lehtonen et al., 1980; Zondek and Zondek, 1979). Most of the prostatic buds emerge from the UGE in the gutters, lateral to the verumontanum (Fig. 20.18). The craniocaudal extent of the verumontanum and the location of emergent prostatic buds are best appreciated through examination of the adult prostate gland (Fig. 20.19).

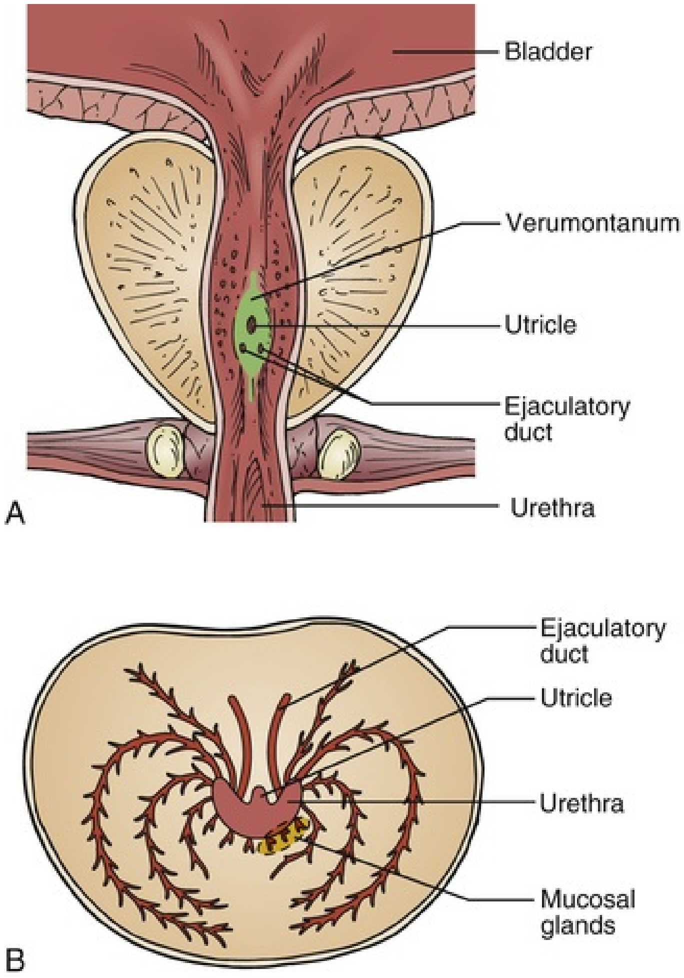

FIG. 20.19 Drawings of adult human prostate. (A) Anterior wall of the urethra has been removed to visualize the verumontanum *(green)* and the posterior and lateral walls of the prostatic urethra. Note the distribution of openings of the prostatic ducts in the "gutters" lateral to the verumontanum as described previously (Timms, 1997). (B) Drawing of a transverse section through the verumontanum of an adult human prostate showing the prostatic utricle and ejaculatory ducts joining the prostatic urethra. The prostatic ducts emerge from the urethra in the gutters lateral to the verumontanum. Mucosal glands emerge from the ventral aspect of the urethra. (From Cunha GR, Vezina CM, Isaacson D, et al. New insights in the development of the human prostate. *Differentiation* 103:24–45, 2018.)

Based on studies in mice, prostatic bud initiation is stochastic with cords of UGE cells emerging into the mesenchyme and receding throughout the budding process. This appears to also apply to human prostatic development as ventral prostatic buds reported in the human fetal prostate (Lowsley, 1912) are not represented in the adult prostate (McNeal, 1981). Prostatic bud growth and subsequent branching morphogenesis occur from approximately 11 weeks onward in a specific spatial pattern that eventually establishes the zonal subdivisions of the mature mouse, rat, and human prostate (Hayashi et al., 1991; Sugimura et al., 1986a; Timms, 2008; Timms and Hofkamp, 2011). The mouse and rat prostate are organized into anterior, lateral, dorsal, and ventral lobes, and ductal branching patterns differ greatly among lobes (Hayashi et al., 1991, Sugimura et al., 1986a). One manifestation of differences in ductal branching patterns is the distance from the prostatic urethra to the first ductal branch point. In the rat and mouse prostate, this distance is short for the ventral prostate and many-fold longer for the dorsal and lateral prostates (Hayashi et al., 1991; Sugimura et al., 1986a). We suspect that this is also true for the human prostate. Measurements from serial sections of the distance from the human fetal prostatic urethra to the first branch point is short in some areas (~250 µm; see Fig. 21.19A). Thick (0.5-mm) coronal sections of human fetal prostate reveal ducts with an initial branch point approximately 1000 µm from their origin from the urethra (see Fig. 21.19B; Cunha et al., 2018a). This approximately fourfold difference in ductal length to the first branch point is consistent with the idea that ductal branching patterns in the human prostate may be lobe specific, as is the case for mice and rats.

The solid prostatic "ducts" subsequently canalize from their proximal urethral connections, distally toward the ductal tips. "Ductal" canalization is associated with the differentiation of luminal and basal cells each expressing its unique profile of differentiation markers (Table 20.1) (Wang et al., 2001). The prebud UGE and "solid prostatic ducts" (before canalization) coexpress markers characteristic of both luminal and basal epithelial cells (see Table 20.1). Accordingly, it appears that epithelial cells destined to become luminal cells maintain luminal cell markers while losing basal cell markers, and epithelial cells destined to become basal cells preserve basal cell markers while losing luminal cell markers (Wang et al., 2001; see Table 20.1).

Modified from Wang Y, Hayward S, Cao M, et al. Cell differentiation lineage in the prostate. *Differentiation.* 2001;68(4–5):270–279.

While prostatic ducts are elongating and undergoing branching, prostatic mesenchyme (UGM) differentiates into smooth muscle, and eventually adult prostatic stroma is mostly composed of smooth muscle (McNeal, 1983). Differentiation of UGM into smooth muscle occurs initially in ventral UGM, with smooth muscle differentiation subsequently spreading into lateral and dorsal areas (Fig. 20.20). It is perhaps worth noting that at 19 weeks ductal branching is most intense near the prostatic capsule, where smooth muscle is particularly abundant (Fig. 20.21; Cunha, et al., 2018b). Does this mean that prostatic smooth muscle plays a role in ductal branching morphogenesis?

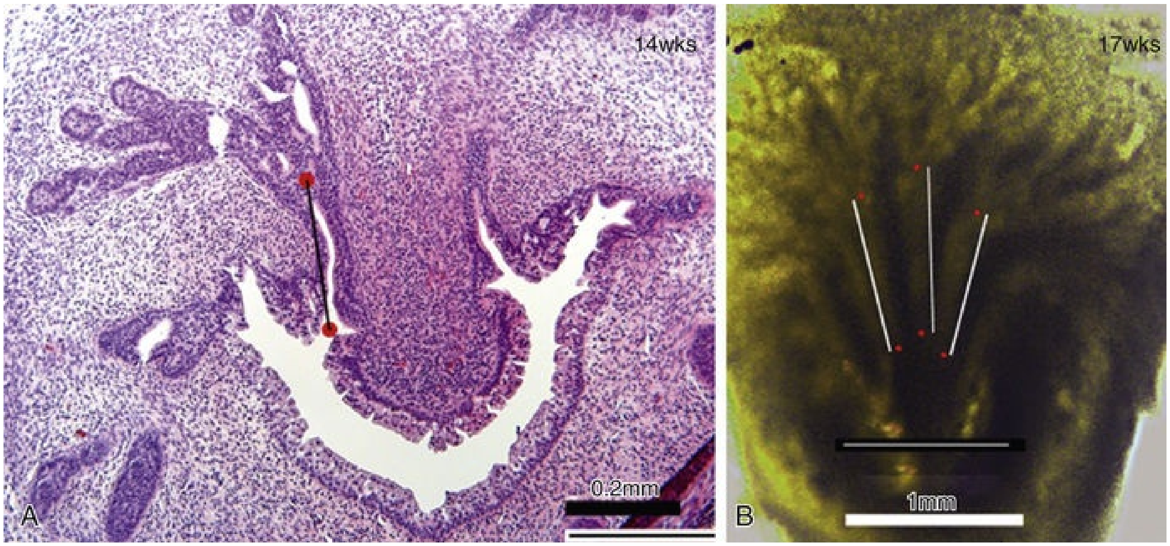

FIG. 20.20 (A) Section of human fetal prostate at 14 weeks' gestation. The *red dots* indicate the proximal origin of a prostatic duct from the urethra and the first branch point, respectively. The distance between these two points is approximately 250 µm. (B) Thick (0.5 mm) coronal section of a 17-week human fetal prostate photographed with transmitted light. *Red dots* are placed on three prostatic ducts depicting ductal length to the first branch point. In all three cases, the distance is approximately 1000 µm. The *thin white line* in (B) representing one of the three white lines above is approximately 1000 µm. (From Cunha GR, Vezina CM, Isaacson D, et al. New insights in the development of the human prostate. *Differentiation* 103:24–45, 2018.)

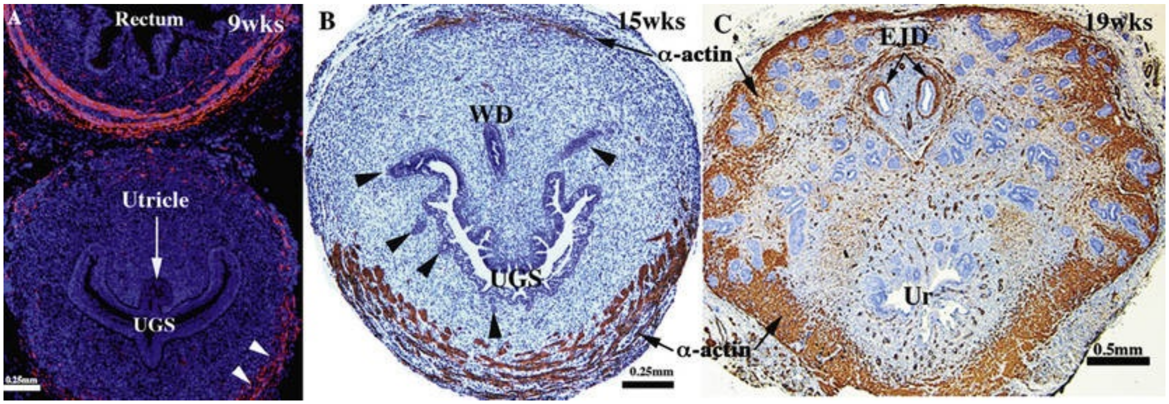

FIG. 20.21 Transverse sections of developing human prostate immunostained for smooth muscle α-actin. (A) Section through the verumontanum of a 9-week prebud UGS in which sparse α-actin–positive cells *(white arrowheads)* are seen in ventrolateral UGM. In contrast, α-actin–positive cells are abundant in the wall of the rectum. (B) Section of a human fetal prostate exhibiting smooth muscle bundles in ventral UGM at 15 weeks' gestation, with minimal α-actin positivity in the dorsal position. (C) Section of a human fetal prostate at 19 weeks' gestation showing α-actin–positive smooth muscle around the periphery, where solid "ducts" are branching. *EJD,* Ejaculatory ducts; *UGS,* urogenital sinus; *Ur,* urethra; *WD,* Wolffian duct.

The endocrinology of prostatic development emerged initially from animal studies (Jost, 1953; Price and Ortiz, 1965). **Androgens produced by fetal testes play a critical role in development of the prostate.** Morphogenetic/differentiation responses to androgens are mediated by nuclear androgen receptors (ARs) that are activated by either testosterone or DHT. The requirement of androgens in prostatic development comes primarily from the absence of prostate in mice and humans lacking functional ARs (Wilson et al., 1983) and from the development of the prostate in the female UGS exposed to androgens (Cunha, 1975). Although testosterone can activate ARs in the UGS by directly binding to the AR, the more potent androgen, DHT, plays a critical role in prostatic development. DHT is produced within the developing UGS by 5α-reductase 2 (5αR2; Russell et al., 1993; Russell and Wilson, 1994). DHT has a 10-fold greater affinity for the AR than testosterone (Deslypere et al., 1992). 5αR2 plays an important role in prostate and male external genitalia development (Andersson et al., 1991; Russell and Wilson, 1994) insofar as prostates of patients with 5αR2 deficiency are rudimentary (Imperato-McGinley and Zhu, 2002; Radmayr et al., 2008). Likewise, transgenic mice lacking steroid

5αR1 and 5αR2 have smaller prostates and seminal vesicles than controls (Mahendroo et al., 2001). 5αR2 is predominantly expressed in prostatic mesenchyme (Radmayr et al., 2008). The function of 5αR1 in urogenital development remains unclear as cloning and genetic studies demonstrate that the *5αR1* gene is normal in patients with 5αR2 deficiency (Andersson et al., 1991).

Mesenchymal-epithelial interactions play a fundamental role in development of the prostate, even though the overall developmental process is elicited by androgens via the AR. Under the influence of androgens, UGM induces and specifies prostatic development in the epithelium. Indeed, UGM can instructively induce prostatic development in embryonic and adult bladder epithelium of rodent and human origin (Aboseif et al., 1999; Cunha et al., 1980, 1983). Mesenchymal-epithelial interactions in the developing prostate are reciprocal. The presence of prostate epithelium plays a critical role in the differentiation of UGS mesenchyme into the periductal prostatic smooth muscle cells (Cunha et al., 1992; Hayward et al., 1998).

The role of mesenchymal versus epithelial AR in prostatic development was determined through use of tissue recombinants prepared with epithelium and mesenchyme from wild-type and AR-negative testicular feminization (Tfm) mice (wt-UGM+Tfm-UGE; Cunha and Lung, 1978). Analysis of chimeric prostates composed of AR-positive wild-type mesenchyme plus Tfm epithelium has demonstrated that AR-deficient Tfm epithelium (UGE or bladder epithelium) can undergo androgen-dependent ductal morphogenesis, epithelial proliferation, and columnar cytodifferentiation (Cunha and Lung, 1978; Shannon and Cunha, 1984; Sugimura et al., 1986b). The fact that mesenchymal (but not epithelial) ARs are required for prostatic ductal growth, branching, and columnar cytodifferentiation suggests that paracrine signals from UGM mediate the action of androgens on the epithelium. However, it is notable that in wt-UGM+Tfm bladder epithelium tissue recombinants, the AR-negative Tfm epithelium failed to express prostatic secretory proteins (Donjacour and Cunha, 1993). Therefore, ductal growth and branching morphogenesis is dependent on paracrine signals from AR-positive mesenchyme, and expression of secretory proteins requires epithelial AR.

Prostate development/differentiation is adversely affected by estrogenic compounds (Prins et al., 2006; Risbridger et al., 2001a; Timms et al., 2005; vom Saal et al., 1997). One acute effect of exogenous estrogen on prostatic development is squamous metaplasia, which is elicited by diethylstilbestrol (DES) in wild-type mice and estrogen receptor beta (ESR2) knockout mice, but not in estrogen receptor alpha (ESR1) null mice (Risbridger et al., 2001b), suggesting that prostatic squamous metaplasia is elicited via ESR1. The roles of epithelial (E) versus stromal (S) ESR1 in DES-induced prostatic squamous metaplasia were assessed as indicated in Table 20.2. Prostatic epithelial squamous metaplasia only occurred in wt-S+wt-E tissue recombinants. Thus, prostatic squamous metaplasia requires ESR1 simultaneously in both the epithelium and stroma.

ESR1 null	ESR1 null	–

Several candidate genes have been implicated in prostatic development. Stimulation of prostatic ductal growth and branching has been attributed to a variety of growth factors and growth factor regulators. Fibroblast growth factor-7 (FGF7 and FGF10, both of which play an important role in prostatic development, are produced by UGM and signal through receptors in developing prostatic epithelium (FGFR2-IIIb) to stimulate growth and branching of prostatic ducts (Donjacour et al., 2003; Finch et al., 1995, Sugimura et al., 1996; Thomson and Cunha, 1999). Activin-A and its antagonist, follistatin, also play a role in regulating prostate epithelial development (Cancilla et al., 2001; Risbridger and Cancilla, 2000). In vitro studies showed that activin-A inhibits prostatic ductal branching and growth, and follistatin increases ductal branching (Cancilla et al., 2001). Thus, prostatic ductal growth and branching may result from a balanced interplay between activin-A and its antagonist follistatin. Other TGFβ family members, bone morphogenetic proteins 4 and 7 (BMP4 and BMP7), restrict ductal branching in developing prostate (Grishina et al., 2005; Lamm et al., 2001). Another growth factor implicated in prostatic development is insulin-like growth factor-1 (Ruan and Kleinberg, 1999; Ruan et al., 1999).

The homeobox gene, *Nkx3.1*, is one of the earliest markers of developing and adult prostatic epithelium in mice (Bhatia-Gaur et al., 1999; Tanaka et al., 2000) and in adult human prostate (Ornstein et al., 2001). Hox homeobox genes are also involved in differentiation of male accessory sex glands (Podlasek et al., 1997, 1999). Hoxa-13 and Hoxd-13 are expressed in the embryonic UGS, and loss of function of these genes in mice results in bulbourethral gland agenesis and defective prostate and seminal vesicle development (Podlasek et al., 1997, 1999). p63 is a marker expressed in embryonic UGE and later in prostatic basal cells and is required for normal prostatic development and postnatal response to androgen deprivation and androgen replacement (Kurita et al., 2004; Signoretti et al., 2000). Fucosyltransferase-1 has also been implicated in prostatic development. A fucosyltransferase-1–binding monoclonal antibody defines a unique expression pattern in the developing prostate and inhibits growth and ductal branching in explants of neonate rat prostate (Marker et al., 2001). In the prebud stage in mice, androgens stimulate bands of *Edar, Nkx3-1,* and *Wnt10b* mRNAs to appear in anterior, ventral, and dorsolateral prostatic budding zones. These mRNAs are later focally restricted during bud initiation and elongation to nascent prostatic bud tips (Bieberich et al., 1996; Keil et al., 2014a; Sciavolino et al., 1997). In response to androgens, selected buds are stabilized as a result of activating WNT beta-catenin, which subsequently permits elongation of buds within prostatic budding zones while inhibiting buds elsewhere (Allgeier et al., 2010; Mehta et al., 2013). DNA methylation status of E-cadherin plays an important role in prostatic bud elongation. DNA methylation of the E-cadherin promoter during the prebud stage and continuing through bud initiation reduces E-cadherin transcription and increases bud epithelial cell motility (Keil et al., 2014b).

Development of the Human Seminal Vesicle

Development of the human seminal vesicle is so sparsely represented in the literature that a PubMed search on “seminal vesicle, human and development” reveals only two papers. Aumuller and Riva (1992) is the most informative literature. Human seminal vesicle appears as a diverticulum of the WD at about the 10th to the 12th week of gestation. The diverticulum elongates and folds back on itself, thus forming a “hooklike duct” with extensive “side ducts forming during months 4 to 5 of pregnancy” (Aumuller and Riva, 1992). Autonomic innervation of the human fetal seminal vesicles was initially detected by immunohistochemistry in the muscle coat of fetal seminal vesicles at 13 weeks’ gestation (Jen et al., 1995). Malformation and malignancy of human seminal vesicles are extremely rare and include rare cases of seminal vesicle cyst.

Key Points: Prostate Development

- Androgens produced by fetal testes play a critical role in development of the prostate.
- Mesenchymal-epithelial interactions play a fundamental role in development of the prostate, even though the overall developmental process is elicited by androgens via the AR.

Development of the Gonads

The gonads differentiate into testes or ovaries and ultimately produce sperm or oocytes, respectively. They develop in a bilateral pair of longitudinal ridges (gonadal ridges) composed of coelomic epithelium and underlying condensed mesenchyme. During the third week of gestation, primordial germ cells arise in the yolk sac and migrate from along the dorsal mesentery to populate the gonadal ridges located in the lower thoracic and upper lumbar levels (Fig. 20.22). **If primordial germ cells fail to reach the gonadal ridges, the gonads fail to develop.** During the sixth week of gestation, the surface epithelial cells of the genital ridge invade the mesenchyme of the gonadal ridges to form the primitive sex cords. The elongated indifferent gonads within the genital ridge at 7 to 8 weeks are macroscopically indistinguishable in males and females (Fig. 20.23). In the course of development, the testes will become more spherical in shape, and the ovaries will remain oblong. Morphometrics analysis shows that the length of the developing ovary is greater than that of the testis (Shen et al., 2018a).

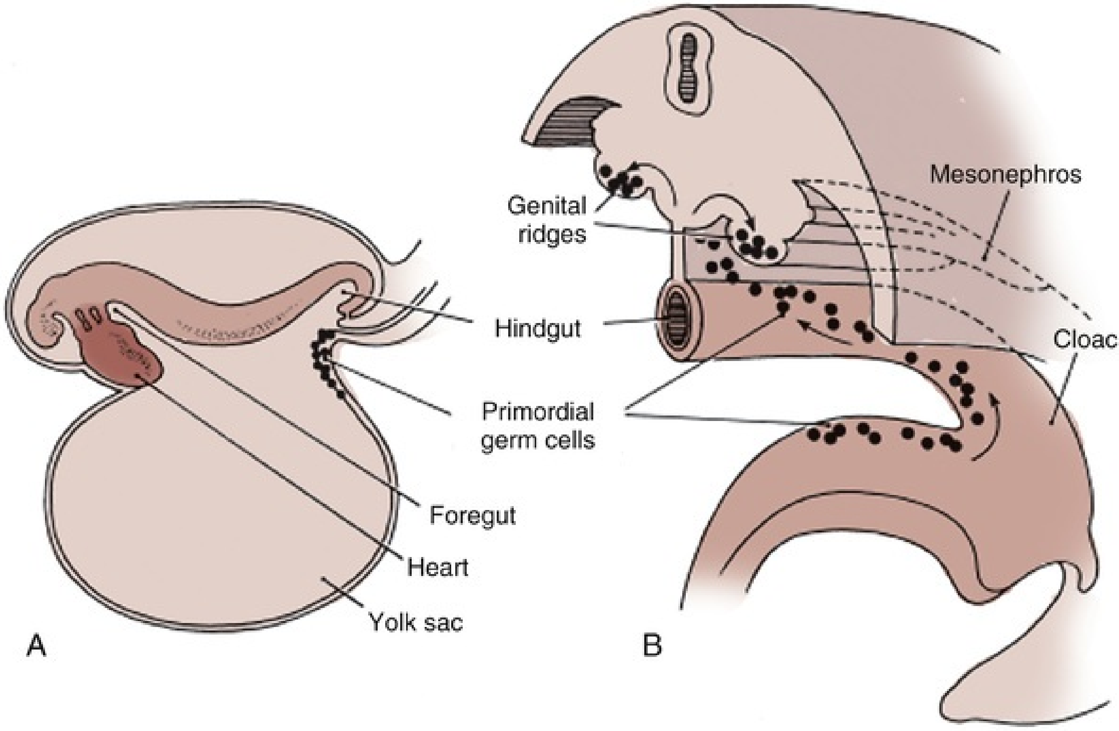

FIG. 20.22 (A) Site of the primordial germ cell origin in the wall of the yolk

sac in a 3-week-old embryo. (B) Migratory path of the primordial germ cells along the wall of the yolk sac and dorsal mesentery into the developing genital ridges. (Modified from Sadler TW. *Langman's medical embryology.* Baltimore, MD: Williams & Wilkins; 1985.)

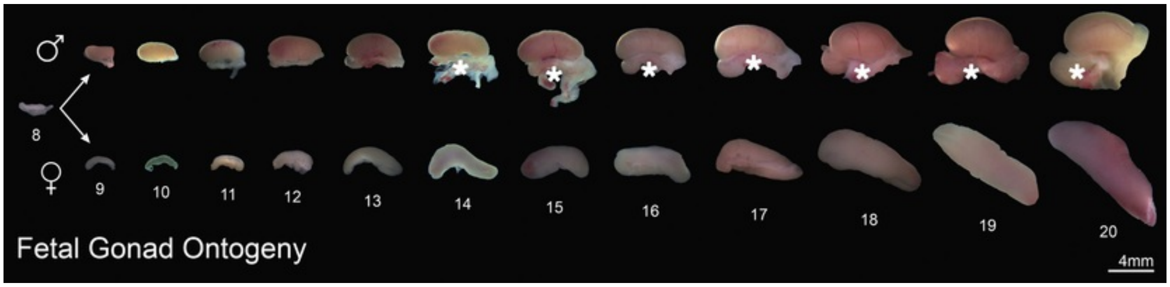

FIG. 20.23 Whole-mount photographs of human fetal gonadal ontogeny. Testis ontogeny *(top row)* and ovarian ontogeny *(bottom row)* are shown. The testis have a more spherical shape in contrast with the oblong shape of the ovaries. Note the epididymal attachments in many testis specimens.

Testicular Formation

Under the influence of SRY gene products, cells in the medullary region will form testicular epithelial cords in which Sertoli cells differentiate in association with primordial germ cells that migrate into these cords (Fig. 20.24; Larney et al., 2014). Sertoli cell differentiation only occurs if SRY protein is present; otherwise the sex cords will form ovarian follicles. These primitive testicular cords containing germ cells eventually will canalize and differentiate into seminiferous tubules in which sperm production will occur. Direct cell-to-cell contact between developing Sertoli cells and primordial germ cells is thought to play a key role in the proper development of male gametes. This interaction occurs shortly after the arrival of the primordial germ cells in the presumptive genital ridge. The testicular cords distal to the presumptive seminiferous tubules also develop lumen and differentiate into a set of thin-walled ducts called the *rete testis*. Just medial to the developing gonad, the tubules of rete testis connect with 5 to 12 residual mesonephric tubules that will form the efferent ductules that will convey sperm to the head of the epididymis. The epididymis and the vas deferens develop from the Wolffian (mesonephric) duct. During the course of development, the shape of the testis changes from oblong to relatively round, reducing its area of contact with the surrounding mesonephros (see Fig. 20.23).

As the testis continues to develop, the *tunica albuginea,* a thick connective tissue capsule subadjacent to its mesothelial surface, lines the testis.

FIG. 20.24 Male and female gonad and genital development. The male and female genital structures are virtually identical through the seventh week. In males, SRY protein produced by the Sertoli cells causes the medullary sex cords to become presumptive seminiferous tubules and causes the cortical sex cords to regress. Müllerian-inhibiting substance (MIS), a glycoprotein hormone produced by the Sertoli cells, then causes the paramesonephric ducts to regress, leaving behind appendix testis and prostatic utricle as remnants. Appendix epididymis and paradidymis arise

from the mesonephric ducts. In females, cortical sex cords invest the primordial germ cells and become the ovarian follicles. In the absence of MIS, the mesonephric ducts degenerate and the paramesonephric ducts give rise to the fallopian tubes, uterus, and upper vagina. The remnants of the mesonephric ducts are found in the ovarian mesentery as the epoöphoron and paroöphoron, and in the anterolateral vaginal wall as the Gartner duct cysts. (Modified from Larsen WJ. *Human embryology.* New York, NY: Churchill Livingstone; 1997.)

As the developing Sertoli cells begin their differentiation in response to the SRY protein, they also begin to secrete a glycoprotein hormone called *Müllerian-inhibiting substance* (MIS; Behringer et al., 1994). **MIS causes the paramesonephric (Müllerian) ducts to regress rapidly between the 8th and 10th weeks of gestation.** Small MD remnants can be detected in males as a small epithelial cysts at the superior pole of the testis, called the *appendix testis.* The prostatic utricle is a small pouching opening on the apex of the verumontanum in the prostatic urethra and is also an MD remnant. In female embryos, MIS is absent; therefore the MDs do not regress and instead form most of the female internal genitalia. **Table 20.3 summarizes the embryologic origin of urogenital structures.**

TABLE 20.3

Embryologic Origin of Urogenital Structures

MALE	EMBRYONIC STRUCTURE	FEMALE
Testis Seminiferous tubules Rete testis (an anastomosing network of delicate tubules located in the hilum of the testicle [mediastinum testis])	Indifferent gonad Cortex Medulla	Ovary Ovarian follicles Rete ovarii (Hilus in which nerves and blood vessels enter the ovary (analogous to rete testis)

During the 9th and 10th weeks, Leydig cells differentiate from mesenchymal cells of the genital ridge in response to the SRY protein (Turner et al., 1995).

These endocrine cells produce testosterone. At an early stage of development, testosterone secretion is regulated by placental chorionic gonadotropin, but eventually fetal pituitary gonadotropins assume control of androgen production. **Between the 8th and 12th weeks, testosterone secretion by Leydig cells stimulates the mesonephric (Wolffian) ducts to transform into the paired epididymis, vas deferens, and seminal vesicle.** The cranial portions of the mesonephric ducts degenerate, leaving a small cystic remnant called the *appendix epididymis.* During the ninth week, five to twelve mesonephric tubules in the region of the epididymis make contact with the developing rete testis. It is not until the third month, however, that communication is established among the developing seminiferous tubules, rete testis, efferent ductules, and the epididymis. Meanwhile, mesonephric tubules near the inferior pole of the developing testis degenerate, sometimes leaving epithelial remnants, called the *paradidymis* (see Table 20.3).

Ovarian Formation

Female embryos lacking a Y chromosome do not elaborate SRY protein and therefore do not differentiate cords containing Sertoli cells. In the absence of Sertoli cells and SRY protein, MIS synthesis, Leydig cell differentiation, and androgen production do not occur. Consequently, masculinization of the genital ducts and accessory glands is not stimulated, and instead female development ensues. In females, the primitive sex cords break up into irregular cluster into which the germ cells migrate to form ovarian follicles. The germ cells differentiate into oogonia and enter the first meiotic division as primary oocytes during fetal life. The follicle cells then arrest further germ cell development until puberty, at which point individual oocytes resume gametogenesis in response to a monthly surge of gonadotropins.

Gonadal Descent

Morphologically, the human urogenital ridge is identical in both sexes at 7 to 8 weeks' gestation. **Before gonadal differentiation, the testis lies near the developing kidney in the upper lumbar region, loosely held in place by two ligamentous structures.** The cranial ligament is referred to as the *cranial suspensory ligament (CSL),* whereas the caudal ligament later develops into the gubernaculum (Fig. 20.25). Between 10 and 15 weeks, the testis has descended to the future inguinal region during the enlargement of the abdominal cavity, and the ovary only descends into the pelvis. The testis is anchored near the inguinal region by enlargement of the gubernaculum and regression of the CSL. As early as the 1700s, enlargement of the gubernaculum in males was observed to tether the testis near the groin while the kidney migrated cranially (Wyndham, 1943; van der Schoot, 1993). In females, the CSL continues to develop, keeping the ovary close to the kidney while the gubernaculum remains rudimentary. In males, androgen induces resorption of the CSL, and the gubernaculum enlarges to become a plump ligamentous body, "holding" the testis in the inguinal region. Starting in the seventh month, the gubernaculum begins to bulge beyond the external inguinal ring and extends into the scrotal location, and simultaneously it is hollowed out by the evaginating peritoneal diverticulum called the *processus vaginalis* (Heyns, 1987). The processus vaginalis allows the intra-abdominal testis to exit the abdominal cavity. The bulky distal end of the gubernaculum (known as the *bulb*) is resorbed in humans after completion of inguinoscrotal migration.

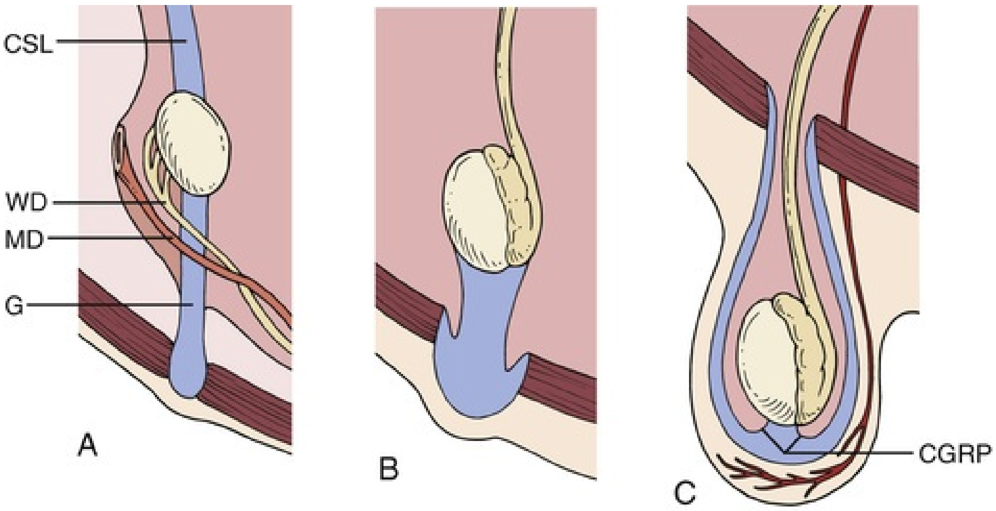

FIG. 20.25 The two stages of testicular descent. (A) Before descent, the developing testis is held in the urogenital ridge by the cranial suspensory ligament *(CSL)* cranially and the gubernaculum *(G)* caudally. The adjacent Wolffian duct *(WD)* forms the epididymis and vas deferens in the male, and the Müllerian duct *(MD)* forms the uterus and tubes in the female. (B) At the end of the transabdominal phase (*15 weeks), the testis is held near the future inguinal ring by the swelling reaction in the gubernaculum. The skin just beyond the gubernaculum is over the future external inguinal ring, as the scrotum is remote in the perineum of humans. (C) The inguinoscrotal phase requires the gubernaculum to elongate to the scrotum, under control

of androgens and calcitonin gene–related peptide *(CGRP)* released from the genitofemoral nerve (GFN). After migration is complete, the peritoneum of the processus vaginalis (PV) closes and then completely involutes and disappears. (Modified from Hutson JM, Li R, Southwell BR, et al. Regulation of testicular descent. *Pediatr Surg Int.* 2015;31[4]:317–325).

Caudal enlargement of the gubernaculum during the early relative transabdominal movement of the testis is known as the *swelling reaction* or *gubernacular outgrowth* (see Fig. 20.25). The gubernacular cord appears to shorten during this process as it becomes incorporated into the enlarging bulb (Wensing, 1986). Shortening of the cord may be an important mechanism to position the testis over the inguinal ring to permit abdominal pressure to push the testis out of the abdomen (Attah and Hutson, 1993; Husmann and Levy, 1995; Quinlan et al., 1988). Transection of the gubernacular cord can lead to either accidental testicular descent into the contralateral inguinal canal or an aberrant intra-abdominal location (Attah and Hutson, 1993; Beasley and Hutson, 1988; Frey and Rajfer, 1984).

The role of intra-abdominal pressure is controversial during the initial transabdominal descent but is thought to be important during transit through the inguinal canal and the subsequent scrotal migration (see Fig. 20.25). Androgens act mostly indirectly via the genitofemoral nerve, which produces calcitonin gene–related peptide (CGRP) to control the direction of migration of the testis (Hutson and Donahoe, 1986).

Inguinoscrotal descent requires migration of the gubernaculum over a considerable distance, along with an increase in length of the processus vaginalis. The force for movement may come from the intra-abdominal pressure, transmitted directly and indirectly to the testis via the lumen of the processus vaginalis and the gubernacular cord, respectively.

Although patients with defective androgen production or androgen metabolism show varied manifestations of cryptorchidism, the exact role of androgen in testicular descent still remains unclear. During intra-abdominal testicular descent, androgen appears to play a role in the regression of the CSL (van der Schoot, 1992). Gubernacular enlargement, in contrast, seems to occur independent of androgen activity, based on the fact that it occurs in androgen-resistant mice and humans (Hutson and Donahoe, 1986). The second migratory step—the inguinoscrotal phase—is thought to be androgen dependent. Migration of the gubernaculum beyond the inguinal region is absent in gonadotropin-deficient mice (Grocock et al., 1988) and those with complete androgen resistance (Hutson, 1986). Regression of the gubernacular bulb after the completion of scrotal descent also appears to be androgen dependent because the gubernaculum remains enlarged in humans with androgen resistance (Hutson and Donahoe, 1986).

INSL3 was identified as a novel gene product of the Leydig cells in 1993 (Adham et al., 1993). INSL3 is similar in structure to the peptide hormones relaxin or insulin and is expressed in both fetal and adult Leydig cells in a differentiation-dependent manner (Balvers et al., 1998) Mice lacking a functional *Insl3* gene demonstrate intra-abdominal cryptorchidism but otherwise no obvious defects in other male reproductive organs. Of more importance, early surgical correction of the cryptorchidism in these mice can restore normal fertility potential (Nef and Parada, 1999; Zimmermann et al., 1999). These are important findings because they reflect the phenotype most commonly observed in classic cryptorchidism in humans.

The ovaries also descend and become suspended within the broad ligament of the uterus. As in males, the female embryos develop a gubernaculum-like structure extending initially from the inferior pole of the ovary into the subcutaneous fascia of the presumptive labioscrotal folds. This “female gubernaculum” later penetrates the abdominal wall as part of a fully formed inguinal canal and becomes the round ligament of the uterus. **In females, although the gubernaculum does not shorten like that in males, it still causes the ovaries to descend during the third gestational month (by anchoring the ovaries in the pelvis) and places them attached to the peritoneal fold (the broad ligament of the uterus).** This translocation of ovaries appears to occur during the seventh week, when the gubernaculum becomes attached to the developing paramesonephric (Müllerian) ducts. As the paramesonephric ducts fuse to form the midline uterovaginal canal, the female gubernaculum becomes tethered to the developing uterus. In this fashion, the female gubernaculum becomes divided into two parts: (1) the segment that extends from the ovary to the uterus called the *ligament of the ovary* and (2) the segment that extends from the uterus through the inguinal canal and into the labia majora called the *round ligament of the uterus.* As in males, the processes vaginalis within the inguinal canal is normally obliterated, but occasionally it remains patent to become an indirect inguinal hernia (Fig. 20.26).

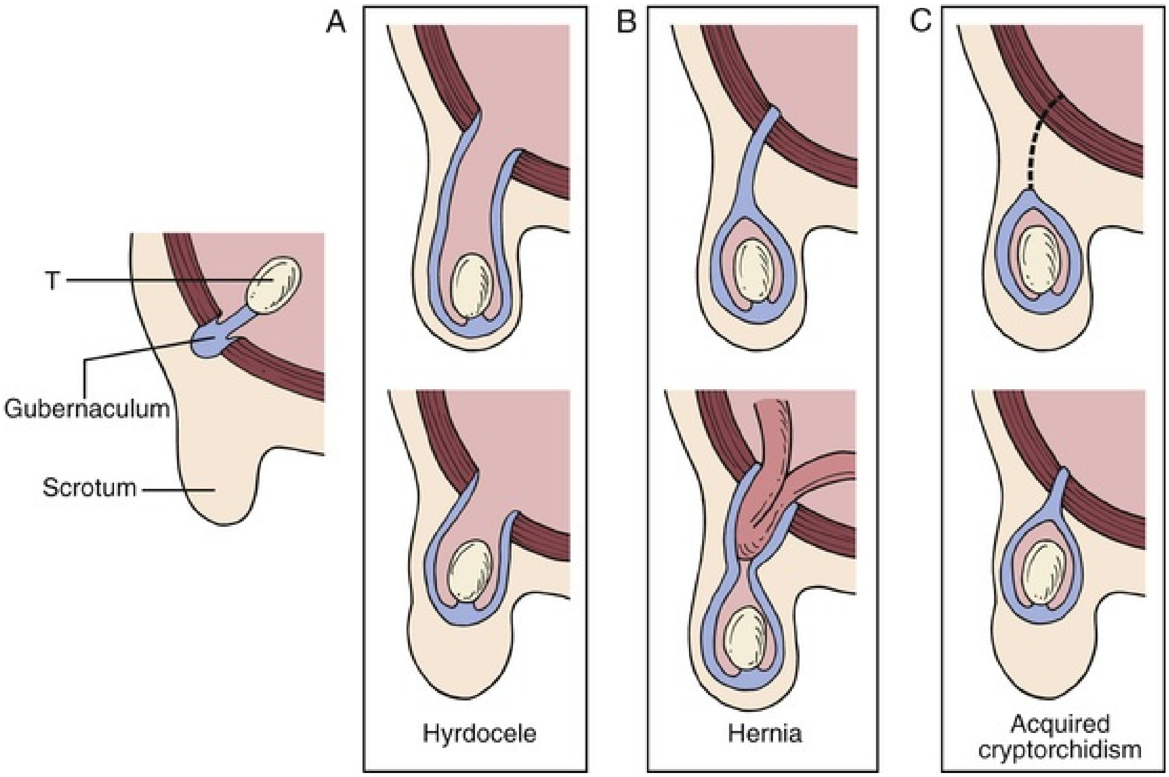

FIG. 20.26 Schematic depicting inguinoscrotal testicular descent and embryology explanation for congenital cryptorchidism, hydrocele, hernia, and acquired cryptorchidism (ascending testis [*T*]). At the end of the transabdominal phase, the enlarged gubernaculum occupies the future inguinal canal, and must migrate 3 to 5 cm to the scrotum (A, step 1), taking the testis inside the processus vaginalis, which elongates inside the gubernaculum. Failure of this first step causes congenital cryptorchidism. After migration is complete, the processus vaginalis closes (B, step 2), and failure of this causes inguinal hernia or hydrocele. The final process (C, step 3) is complete involution of the processus vaginalis remnant, allowing the spermatic cord to elongate after birth. Failure of this step is the likely cause of acquired cryptorchidism, as the fibrous remnant of the processus vaginalis prevents the spermatic cord growing normally. (Modified from Hutson JM, Li R, Southwell BR, et al. Regulation of testicular descent. *Pediatr Surg Int.* 2015;31[4]:317–325).

Clinical Correlation: Cryptorchidism

Cryptorchidism occurs in approximately 3% of newborn males (Fig. 20.27AB; Gurney et al., 2017). Hydroceles and hernia are even more common (Chan et al., 2016). An understanding of the mechanism of testicular descent affected or regulated via the CSL, gubernaculum, and processes vaginalis can explain the embryology of undescended testis, hydrocele, hernia, and acquired cryptorchidism (see Fig. 20.26). In the case of abnormal retention of the cranial suspensory ligament, the undescended testis is likely to be found in the abdomen (see Fig. 20.27AB). Abnormalities in the gubernacular attachment are likely to result in undescended testis located in the inguinal canal area or externally if the gubernacular attachment is ectopic in the perineum, femoral area, or near the penis. **Abnormalities in closure of the processes vaginalis can result in hydrocele or hernia, and lack of complete involution of the processus vaginalis can result in acquired cryptorchidism** (see Fig. 20.26C; Hutson and Donahoe, 1986).

(E) Ovotestis in ovotesticular syndrome. (F), Retained Müllerian structures in gonadal dysgenesis (orange testis syndrome).

Clinical Correlation: Streak Gonad

Streak gonads typically occur with three genotypes (see Fig. 20.27D): (1) 45,XO (Turners syndrome; Hook and Warburton, 2014); (2) 46,XX (gonadal dysgenesis; Lee, Nordenstrom et al., 2016; Mouriquand et al., 2016); or (3) 46,XY (gonadal dysgenesis; Massanyi et al., 2013). The condition results if there is an absence of both MIS and testosterone. The absence of testosterone results in regression of WD, and hence normal male internal reproductive tracts will not develop. The absence of MIS allows the MDs to differentiate into the fallopian tubes, uterus, cervix, and upper vagina (see Fig. 20.27E). These patients have female-like internal and external genitalia and will require hormonal replacement for the nonfunctional streak gonad for development of secondary sex characteristics. **Patients with 46, XY genotype are at risk for gonadoblastoma and subsequent malignancy and therefore typically have the streak gonads removed** (Cools, 2014).

Clinical Correlation: Ovotesticular Syndrome

The presence of both ovaries and testis (Ovotestis) in humans is an extremely rare condition in which the gonad differentiates into both testicular and ovarian tissue (see Fig. 20.27E; Lee et al., 2016; Mouriquand et al., 2016). During fetal development and postnatally, both the testicular and ovarian tissue can function hormonally, although in contrast with potential female fertility with normal oocytes, functioning spermatogenesis in adulthood has not been reported. During fetal development, internal duct development usually corresponds to that of the adjacent gonad. MD structures typically develop on the gonad side(s) not containing testicular tissue. WD structures tend to be observed on the gonadal side(s) containing functioning testicular tissue. Patients born with ovotesticular syndrome often have atypical genitalia.

Clinical Correlation: Persistent Müllerian Duct Syndrome

Rarely, genetic males (XY) may have persistent MD structures (uterus and fallopian tubes), a condition known as *hernia uteri inguinale* (see Fig. 20.27F; Salehi et al., 2012). This typically results from abnormalities in the MIS receptor, thus eliminating MIS action and retained female internal genitalia in the setting of a relatively normal male phenotype. Clinically this can be found in patients undergoing exploration for bilateral abdominal testis. **Retained Müllerian structures can also result from immature development of the testis in which the timing of MIS production is out of phase with sensitivity of fetal Müllerian structures to MIS, which normally acts between 9 and 13 weeks' gestation.**

Key Points: Gonadal Development

- Under the influence of the *SRY* gene, the indifferent gonads of the ambisexual embryo differentiate into a testis.

- Androgens from the Leydig cell of the fetal testis drive male genital differentiation including prostatic development.
- MIS from Sertoli cells of the testis causes degeneration of female Müllerian ductal structures (uterus and fallopian tube).
- Both gonads descend to pelvic location by the third month of gestation, but the testis descends into the scrotum with the aid of the gubernaculum at about the seventh month.

Müllerian Structures (Female Internal Genitalia)

The Müllerian structures are not present in normal males secondary to the secretion of MIS from the testis (Behringer et al., 1994). In females, who lack testosterone, WDs resorb (Blaschko et al., 2012) and MDs are retained and develop into the uterine body, uterine cervix, and fallopian (uterine) tubes (Fig. 20.28). Note that in the whole-mount specimens it is impossible to differentiate the uterine body from the cervix and vagina. As expected, the size of the uterine body increases over time (see Fig. 20.28).

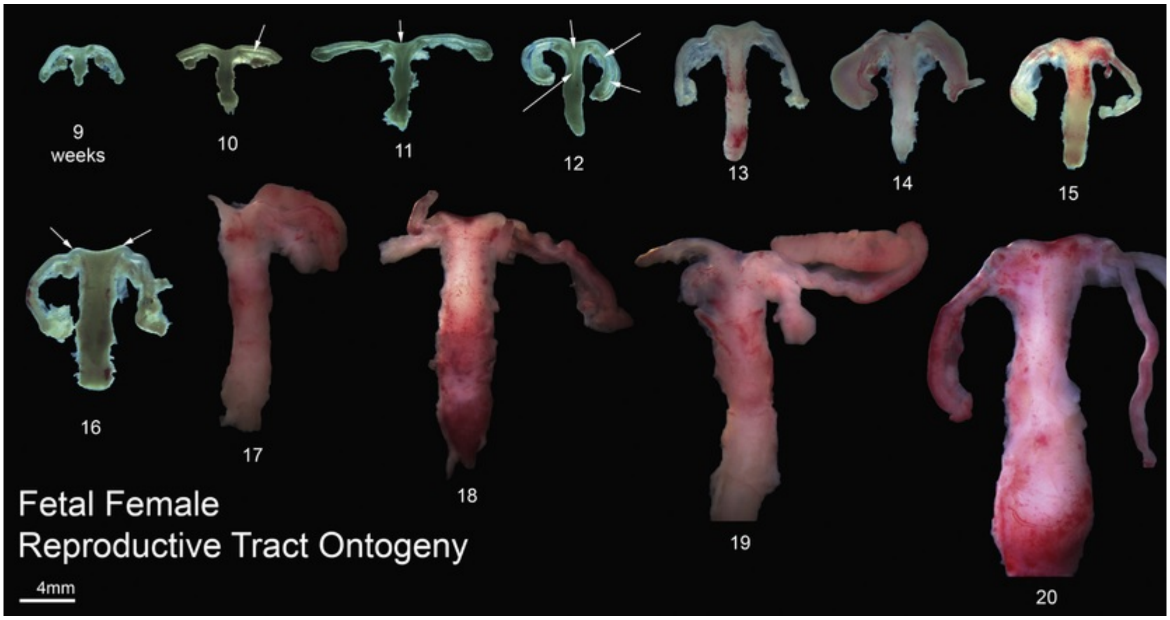

FIG. 20.28 Whole-mount photographs of developing human fetal female internal genitalia at 9 to 20 weeks' gestation. Note the increase in size and morphologic complexity with time, and that landmarks distinguishing the uterine corpus, cervix, and vagina are nonexistent. Specimens photographed with transmitted light (11, 12, and 16 weeks) permit visualization of internal (epithelial) organization in regions not too thick (note the epithelium defining the lumen of the uterine tube and the epithelium lining the uterus).

Development of the Human Female

Reproductive Tract

At the start of week 5 in human female and male embryos, the coelomic epithelium invaginates on the lateral surface of the paired urogenital ridges to initiate MD development (Fig. 20.29; O'Rahilly, 1973). The infoldings later become the tubal ostia of the Müllerian (paramesonephric) ducts. The paired MDs grow caudally within the urogenital ridges using the WDs as “guidewires.” Indeed, the WD is requisite for caudal MD migration to the UGS (Gruenwald, 1941; Kobayashi et al., 2005). Subsequently, the WDs of female fetuses degenerate, leaving vestigial remnants (epoöphoron and paroöphoron) usually found within the broad ligament of the uterus and Gartner's duct within the fibromuscular wall of the vagina (Moore and Persaud, 2003; see Table 20.3). During MD migration, the mesenchyme initially separates the MDs and the WDs (Fig. 20.30). More caudally, the conjoined basement membranes of the MDs and WDs are in contact without intervening mesenchyme. Even more caudally, the tip of the MD is in direct contact with WD (see Fig. 20.30), which led to the idea that the WD may contribute cells to the MD or vice versa (Frutiger, 1969). However, recent cell-lineage tracing experiments in mice do not support this contention (Kurita, 2010).

(From Robboy SJ, Kurita T, Baskin L, Cunha GR. New insights into human female reproductive tract development. *Differentiation.* 2017;97:9–22.)

The WDs and MDs exhibit two gentle curves in route to the UGS that define horizontal and vertical portions, as seen in frontal view (Fig. 20.31). The point of contact of the MDs with the UGS is called the *Müllerian tubercle,* which is poorly described and minimally illustrated in the literature and thus is a term of limited value. During the seventh to eighth weeks, the right and left MDs lie between the two WDs as these ducts approach and join the UGS. In the eighth week, the paired MDs fuse in the midline to form the uterovaginal canal (Fig. 20.32). During fusion, the paired MDs become separated by a midline epithelial septum, which disappears in the ninth week (Hunter, 1930; Koff, 1933; see Fig. 20.32, *inset*).

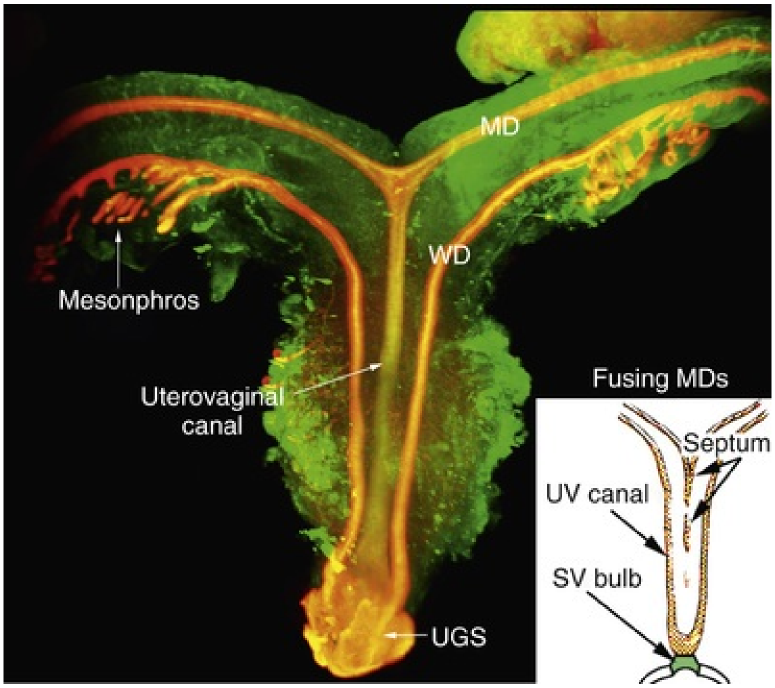

FIG. 20.32 Light sheet microscopy of a human female reproductive tract at 9.5 weeks (indifferent stage) stained with an antibody to E-cadherin that allows visualization of epithelium. The mesonephros and Wolffian ducts *(WD)* are present at this stage. Cranially, the unfused Müllerian ducts *(MD)* are destined to form the uterine tubes. Midline fusion of the MDs has created the uterovaginal canal that terminates caudally by joining the urogenital sinus *(UGS).* Inset depicts MD fusion to form the uterovaginal canal *(UV canal)* and the septum. Note the sinovaginal bulb *(SV bulb, green),* which is a UGS derivative. (From Cunha GR, Vezina CM, Isaacson D, et al. New insights in the development of the human prostate. *Differentiation.* 2018. pii: S0301-4681(18)30099-9. [Epub ahead of print].)

Uterine Tube

The uterine tubes, originally called the fallopian tubes, develop from the paired cranial portions of the MDs retained after the caudal segments fuse to form the midline uterovaginal canal (see Fig. 20.32). Fimbria develop from the irregular ostia of the MDs (see Fig. 20.29). At 8 weeks, the uterine tubes are narrow, and the epithelium defines a circular tubular profile. In the ensuing months, two noticeable changes occur: (1) The mucosa becomes highly folded, most prominently in the infundibulum and ampulla, and (2) the loose mesenchyme surrounding the epithelial tube differentiates into an inner stromal layer associated with the epithelium and outer layer of smooth muscle (Fig. 20.33).

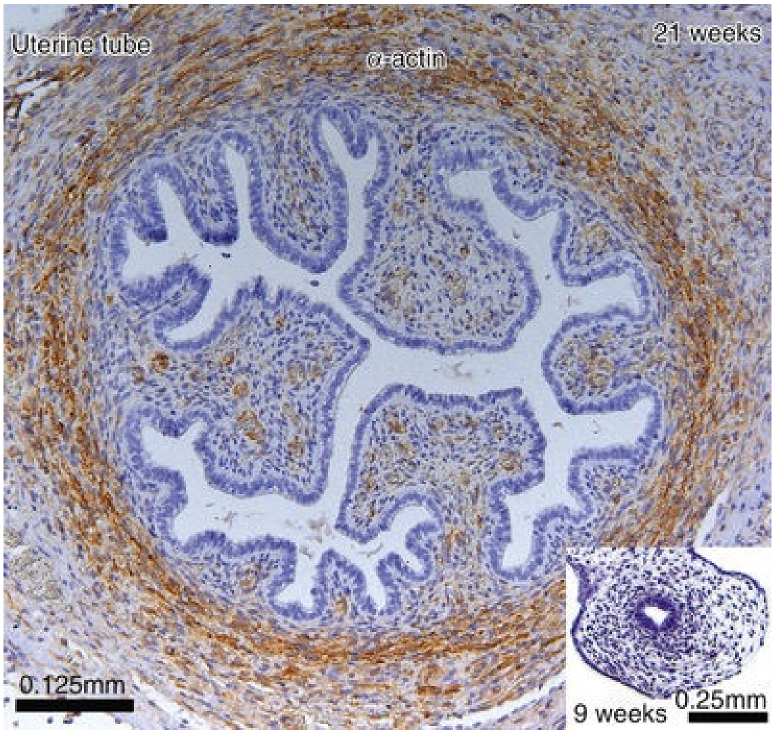

FIG. 20.33 Section of the ampulla of the human uterine tube at 21 weeks stained with an antibody to α-actin. Note the highly folded epithelium. *Inset* is the uterine tube at 9 weeks' gestation.

Uterus Corpus and Cervix

The uterine corpus develops from the cranial portion of the midline uterovaginal canal, which formed as a result of fusion of the MDs (see Fig. 20.32). **Initially a midline epithelial septum represents the zone of fusion of paired MDs that is subsequently eliminated. Failure of regression of the septum can lead to a variety of malformations (see later).** The cranial aspect of the uterovaginal canal forms the uterine corpus and uterine cervix (Fig. 20.34), and the caudal portion of uterovaginal canal is involved in vaginal development. The Müllerian epithelium lining of the cranial aspect of the uterovaginal canal remains simple columnar and eventually forms uterine and cervical glands that penetrate into the endometrial stroma. Cervical epithelium remains simple columnar and glandular cranially in the endocervix, but near the external os of the cervix the Müllerian epithelium differentiates into a stratified squamous epithelium that also covers the exocervix projecting into the vagina. The mesenchymal wall of the uterovaginal canal differentiates into endometrial stroma containing uterine and cervical glands. The endometrial stroma is in turn surrounded by a thick smooth muscle layer, the myometrium, which also differentiates from mesenchyme of the uterovaginal canal.

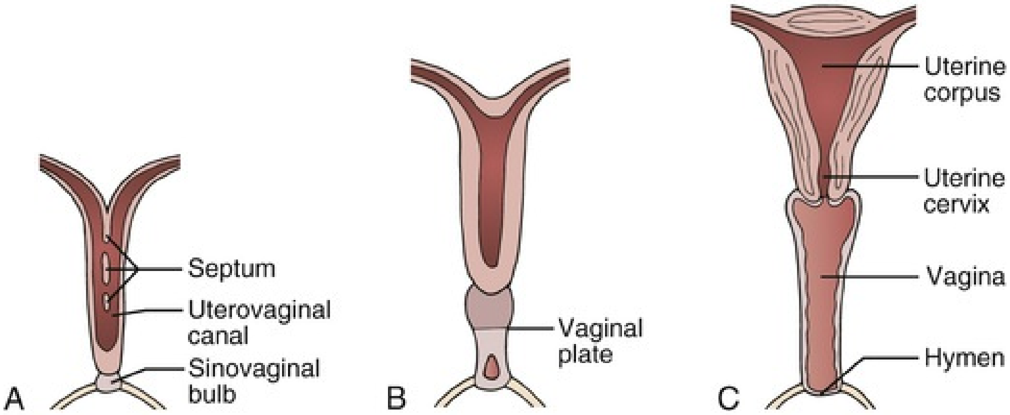

FIG. 20.34 Drawings depicting (A) fusion of the Müllerian ducts to form the uterovaginal canal and contact of the Müllerian epithelium of the uterovaginal canal with the sinovaginal bulb derived from urogenital sinus epithelium (UGE). In (B) the solid vaginal plate has formed from both UGE and Müllerian epithelium. In (C), the UGE has replaced the Müllerian epithelium up to the level of the exocervix.

Vagina

The origin of human vaginal epithelium has been debated for decades. Various investigators have proposed that vaginal epithelium receives contributions from epithelia of the UGS, MDs or WDs alone, or in combination (Koff, 1933; Bulmer, 1957; O'Rahilly, 1977; Forsberg, 1978). The two most popular views on derivation of human vaginal epithelium were advanced by Koff in 1933 and Bulmer in 1957 (Koff, 1933; Bulmer, 1957). Koff proposed that human vaginal epithelium derives from both Müllerian and endodermal epithelium of the UGS that forms the so-called *sinovaginal bulbs* (Koff, 1933). Koff maintained that Müllerian epithelium predominated in human vaginal epithelial development. In contrast, Bulmer proposed that UGS epithelial upgrowth “forms the whole of (the vaginal) epithelial lining.” The conclusions from both studies are based solely on hematoxylin and eosin (H&E)-stained sections.

We have utilized immunohistochemistry to explore the question of the relative contribution of Müllerian versus UGE to human vaginal epithelium. PAX2 is a protein expressed in Müllerian epithelium (Cunha et al., 2018; Kurita, 2010), and FOXA1 is a protein expressed in endodermal UGE and its derivatives

(Besnard et al., 2004; Diez-Roux et al., 2011; Robboy et al., 2017). PAX2 immunostaining was observed in the 8- to 9-week MD and in the uterovaginal canal (Fig. 20.35).

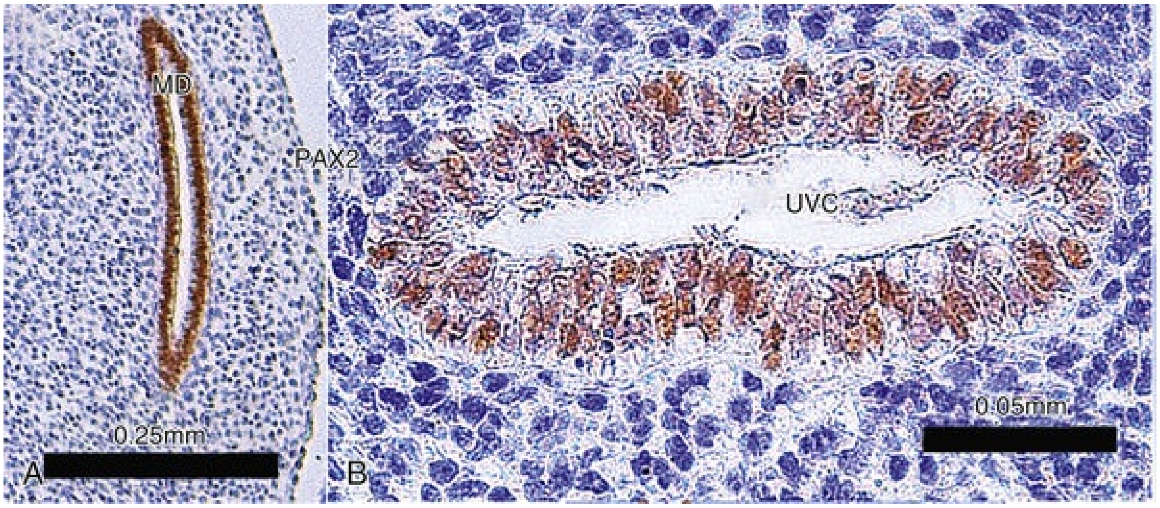

FIG. 20.35 PAX2 immunostaining of the (A) Müllerian duct *(MD)* and (B) uterovaginal canal *(UVC)* at 9 weeks.

The uterovaginal canal initially has a lumen throughout its entire length, but caudally the epithelium of the uterovaginal canal proliferates to form the solid vaginal plate that caudally abuts the endodermal UGS-derived epithelium of the sinovaginal bulbs (see Fig. 20.34). This is illustrated particularly well at 12 weeks, when the cranial (uterine) end of the uterovaginal canal is in continuity with the solid vaginal plate (Fig. 20.36). Both the solid vaginal plate and the uterovaginal canal are PAX2-reactive (see Fig. 20.36AB). In contrast, the caudal portion of the vaginal plate (sinovaginal bulb) is FOXA1-reactive as is the epithelium of the urethra and bladder (see Fig. 20.36CD). During the next several weeks (14 to 21 weeks), the solid vaginal plate increases in extent, and the areas of PAX2 and FOLXA1 reactivity change dramatically consistent with substantial replacement of PAX2-positive Müllerian epithelium by FOXA1-UGE.

FIG. 20.36 Sagittal sections of a 12-week human female fetal reproductive tract immunostained with PAX2 (A and B) and FOXA1 (C and D). PAX2-reactive epithelial cells extend to near the junction with the introitus/urethra (A and B). FOXA1-reactive epithelial cells extend only a short distance into the solid vaginal plate (C and D). Scale bar in (A) also refers to (D). Scale bar in (D) also refers to (C).

Canalization of the solid vaginal plate is initiated in approximately the 15th week and is mostly complete by 18 to 19 weeks (Koff, 1933), when vaginal fornices are well defined with the exocervix projecting into the vaginal vault. At this stage, PAX2 reactivity was seen continuously from the uterine tube to the upper vagina, and FOXA1-positive epithelium had extended cranially to the mid-vagina. At 21 weeks, the vaginal epithelium was many cell layers thick and glycogenated (likely caused by endogenous estrogen; Fig. 20.37AB). Epithelial PAX2 immunostaining was observed in epithelium of the uterine tube, the uterus (see Fig. 20.37D), and the cervix (see Fig. 20.37C). Epithelial FOXA1 staining was observed from the vaginal introitus to the cervix. The abrupt change in FOXA1/PAX2 staining occurred at the same point at the vaginal/cervical junction (see Fig. 20.37EF). **These immunohistochemical data support Bulmer's proposal that the entire human vaginal epithelium is derived from UGE, which is depicted in Fig. 20.34.** The most caudal segment of the vagina at the introitus is FOXA1 positive, and thus the presumption is that the epithelium of the hymen is derived from UGE.

FIG. 20.37 Sagittal sections of a 21-week human female reproductive tract. Because of section orientation, (A) depicts the lower portion of the specimen (the introitus to the upper vagina), and (B) depicts the upper portion of the specimen (vagina, cervix, and uterus) (H&E stain). The vaginal epithelium is many layers thick as a result of estrogenic stimulation (A and B). In (B), note the abrupt transition in epithelial differentiation at the vaginal/cervical border (*). PAX2 staining of the vaginal/cervical border (C) shows prominent PAX2 immunostaining (indicative of Müllerian duct origin) of stratified but relatively thin cervical epithelium and PAX2-negative vaginal epithelium (C). Epithelium of the uterine corpus (D) is strongly PAX2-reactive. FOXA1 immunostaining was seen uniformly throughout the entire vagina, and FOXA1 immunostaining abruptly stopped at the vaginal/cervical border (E and F) in mirror image to PAX2 immunostaining (C). (*) denotes the interface between vaginal and cervical epithelium in (B), (C), and (E).

It is important to recognize that derivation of vaginal epithelium in the mouse is entirely different from that in the human as is the terminology. In the newborn mouse, the upper (cranial) portion of the vagina (called the *Müllerian vagina*) is lined by PAX2-positive Müllerian epithelium that abuts on the solid endodermal “sinus vagina.” Elegant lineage tracing experiments have shown that postnatally the Müllerian vaginal epithelium completely replaces the endodermal sinus vaginal epithelium (Kurita, 2010).

Clinical Correlation: Vaginal Agenesis and Imperforate Hymen

Failure of canalization of the vaginal canal results in atresia or blockage of the vagina. This occurs in approximately 1 : 80,000 women and is called a *transverse vaginal septum*. The septum is typically located at the junction of the middle and superior third of the vagina. **Failure of the inferior end of the vaginal canal to open may be caused by imperforate hymen, which is the most common cause of vaginal obstruction** (Fig. 20.38).

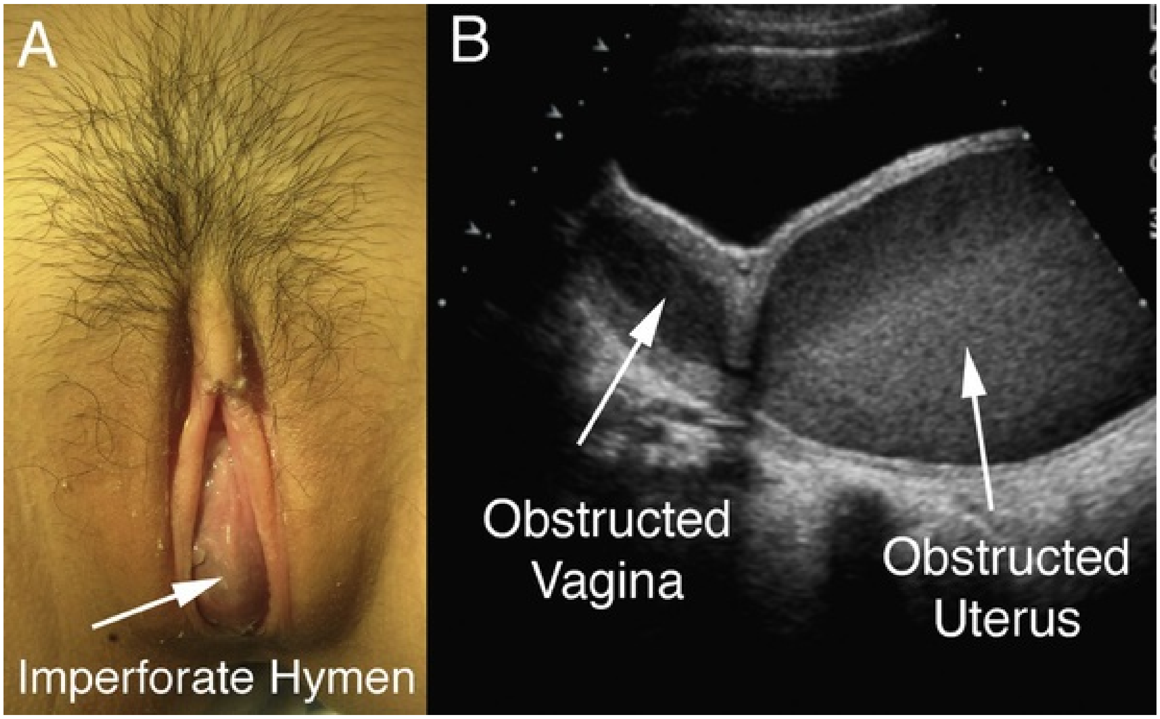

FIG. 20.38 (A) Gross photograph of bulging imperforate hymen in an 11-year-old female patient with cyclic abdominal pain. (B) Sonographic images of the same patient with dilated vagina and uterus.

Clinical Correlation: Uterus Didelphys

Uterus didelphys results from failure of the fusion of the caudal aspects of the Müllerian (paramesonephric) ducts. **A unicornuate uterus develops when one of the MDs fails to develop.**

Clinical Correlation: Obstructed Hemivagina and Unilateral Renal Anomalies

Obstructed hemivagina and ipsilateral renal agenesis (OHVIRA) syndrome is a rare congenital anomaly that involves Müllerian and urinary tract anomalies. OHVIRA syndrome usually presents after menarche with symptoms such as cyclic abdominal pain and vaginal discharge but can present more dramatically with an acute abdomen and tubo-ovarian abscess. More recently, there have been reports of OHVIRA syndrome with ipsilateral dysplastic kidneys or ectopic ureters (Schlomer et al., 2015). OHVIRA syndrome is thought to be caused by abnormal development of the MDs and the WDs (Capito et al., 2008). True renal agenesis can occur because of an absence in WD formation, ureteric bud formation, or metanephric blastemal formation. Findings in females with true renal agenesis also include an absent ipsilateral bladder hemitrigone. Prior studies suggest the reason the ipsilateral kidney is not visualized on imaging in OHVIRA syndrome is not because of true renal agenesis from an absence of WD formation but secondary to renal dysplasia and atrophy caused by abnormal WD formation associated with abnormal ipsilateral MD formation (Kiechl-Kohlendorfer et al., 2011). Usually the distinction between true agenesis versus dysplasia and atrophy does not have clinical implications. However, in cases of OHVIRA syndrome in which the ipsilateral dysplastic and atrophic kidney can lead to persistent vaginal leakage after resection of vaginal septum, we believe that it is important not to assume that renal agenesis is present in OHVIRA syndrome. **Hence, we accept the new terminology that OHVIRA syndrome should stand for obstructed hemivagina and ipsilateral renal anomalies** (Fig. 20.39; Schlomer et al., 2015).

Key Points: Müllerian Development

- Immunohistochemical data support Bulmer's proposal that the entire human vaginal epithelium is derived from UGE (without Müllerian or Wolffian cell origin).
- A midline epithelial septum represents the zone of fusion of paired MDs that is subsequently eliminated. Failure of regression of the septum can lead to uterine obstruction/duplication.
- Failure of the inferior end of the vaginal canal to open can be caused by imperforate hymen, which is the most common cause of vaginal obstruction.

Bladder: Ureteral Development

Both the bladder and ureters consist of a urothelial-lined lumen, a lamina propria consisting of extracellular matrix with unorganized smooth muscle, an outer layer of thick bundles of smooth muscle, and a serosal surface. The ureters and bladders of human males and females develop in similar fashion without differences in size. In contrast, in males the prostate develops below the insertion of the ureters into the trigone (see Fig. 20.15). Thus, in males the prostatic urethra is clearly larger in size than the homologous region in females (Fig. 20.40). The ureterovesical junction inserts into the bladder trigone in exactly the same fashion in both the male and female fetuses (see Figs. 20.15 and 20.40).

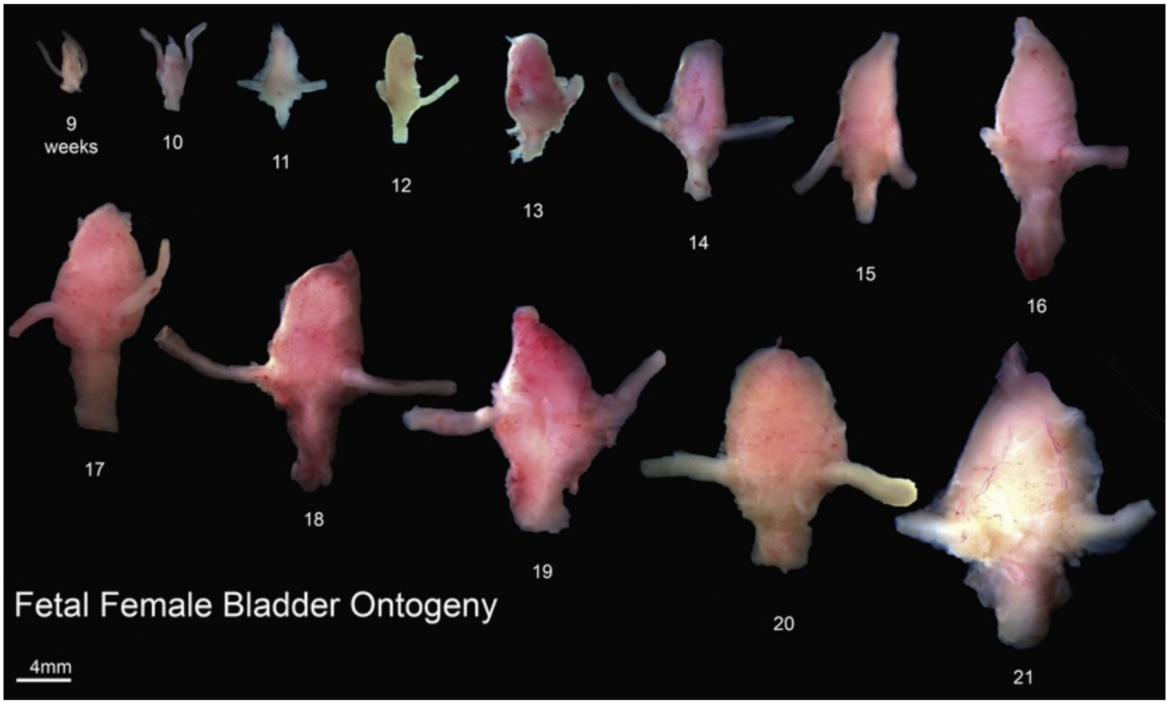

FIG. 20.40 Whole-mount photographs of human female fetal bladders (9 to 21 weeks' gestation). Compare to the male ontogeny (see Fig. 20.15), and note the lack of prostate tissue and vas deferens. Note that the male and female bladder sizes are similar at each gestational age.

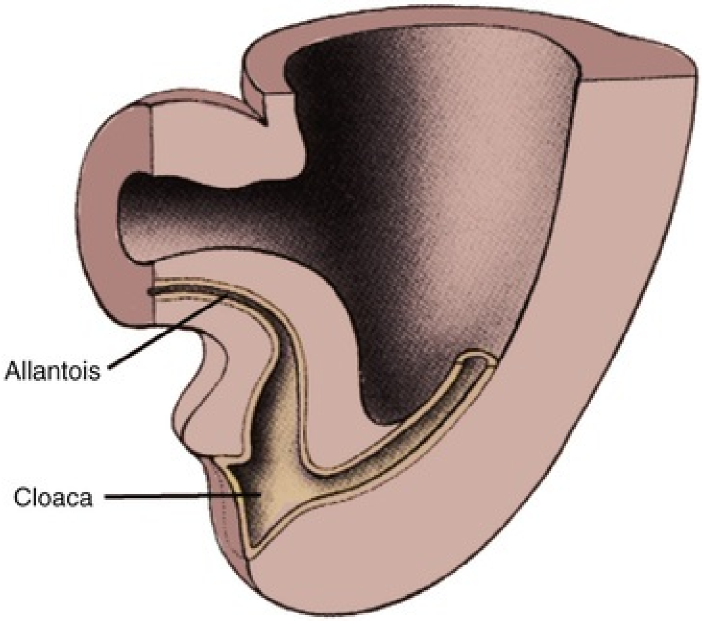
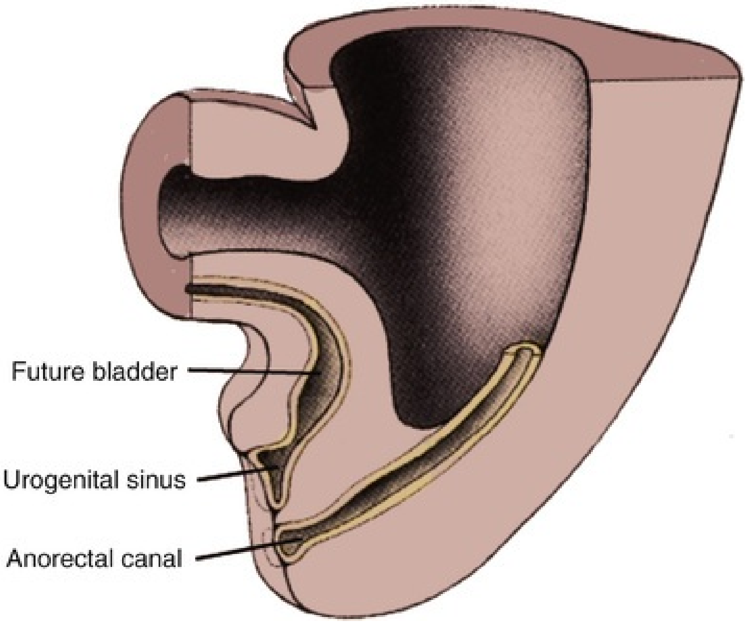
Formation of Urogenital Sinus

At the fifth to sixth week of gestation, the urorectal septum separates the cloacal into the dorsal anorectal canal and ventral UGS (Fig. 20.41) based on the historic observations of Rathke and Tourneux (Rathke, 1832; Tourneux, 1888). Abnormalities in the cloacal membrane (and not the urorectal septum) are thought to lead to anorectal malformations (Fig. 20.42; Nievelstein et al., 1998). Ultimately, the UGS and its diverticulum, the allantois, form the bladder and urethra with the allantois being the embryologic precursor of the urachal remnant.



Allantois
Cloaca



Future bladder
Urogenital sinus
Anorectal canal

FIG. 20.41 Development of the urogenital sinus. Between the fourth and sixth weeks, the cloaca is divided into an anterior urogenital sinus and a posterior anorectal canal. The superior part of the urogenital sinus, continuous with the allantois, forms the bladder. The constricted narrowing at the base of the urogenital sinus forms the pelvic urethra. The distal expansion of the urogenital sinus forms the vestibule of the vagina in females and the penile urethra in males. (Modified from Larsen WJ. *Human embryology.* New York NY: Churchill Livingstone; 1997.)

Cloacal malformation

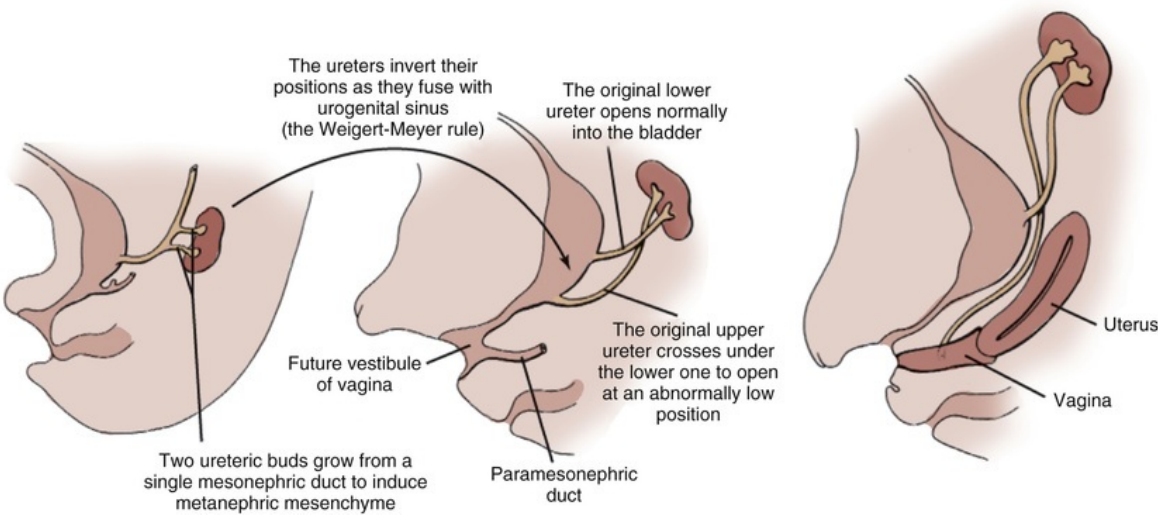
FIG. 20.42 Abnormal development of the cloacal membrane results in characteristic anomalies of the urogenital and lower gastrointestinal tract. (Modified from Larsen WJ. *Human embryology.* New York, NY: Churchill Livingstone; 1997.)

The Wolffian (mesonephric) ducts fuse with the cloaca just before its subdivision by the urorectal septum (Moore et al., 2016; see Table 20.3). The entrance of the mesonephric ducts into the primitive UGS serves as a landmark distinguishing the cephalad vesicourethral canal from the caudal UGS. The vesicourethral canal gives rise to the bladder and pelvic urethra. Early in development, the bladder is continuous with the allantois. The caudal portion of the UGS forms the phallic urethra in males and urethra and vaginal vestibule in females (Moore et al., 2016).

Formation of Trigone

Also, at approximately the fifth or sixth week of gestation, the *common excretory ducts* (the portion of mesonephric ducts distal to the origin of ureteric buds) dilate and connect to the UGS. The formation of these final connections involves apoptosis, which enables the ureters to disconnect from the mesonephric ducts and fuse to the bladder (Batourina et al., 2005). With use of cell-lineage studies (in mice), the fibromuscular wall of the trigone was found to form mostly from bladder smooth muscle cells with only a minor contribution from mesenchymal cells associated with the ureters (Viana et al., 2007). This is in contrast with the classic hypothesis in which the trigone is formed from an extension of the ureteral development into the trigone of the bladder (Weiss, 1988). The ureteral orifices incorporate into the bladder and migrate in a cranial and lateral direction within the base of the bladder.

The embryonic pattern of ureteral orifice incorporation into the developing bladder is inferred primarily from clinical observations of duplex kidneys with two ureters joining the bladder on the same side. The upper-pole ureteral orifice rotates dorsally relative to the lower-pole orifice and assumes a more caudal and medial position. **Weigert and Meyer recognized the regularity of this relationship between upper- and lower-pole ureteral orifices, which has come to be known as the Weigert-Meyer rule (Weigert, 1877; Meyer, 1907). According to this concept, an abnormally laterally placed lower-pole ureteral orifice may result from a ureteric bud arising too low on the mesonephric duct, therefore resulting in premature incorporation and migration within the developing bladder.** In such an abnormal ureteral orifice, vesicoureteral reflux is more likely to occur because of an inadequate intramural tunnel. In contrast, the abnormally caudal upper-pole ureteral orifice may result from a ureteric bud arising too high on the mesonephric duct. It may drain at the bladder neck and verumontanum or remain connected to mesonephric (Wolffian) duct derivatives such as the vas deferens in males (Mackie and Stephens, 1977; Schwarz and Stephens, 1978). **In females, the ectopic upper-pole ureter may insert into the remnants of the mesonephric ducts (e.g., Gartner duct cyst) or the vaginal vestibule** (Fig. 20.43; Glassberg et al., 1984).



The ureters invert their positions as they fuse with urogenital sinus (the Weigert-Meyer rule)
The original lower ureter opens normally into the bladder
The original upper ureter crosses under the lower one to open at an abnormally low position
Future vestibule of vagina
Two ureteric buds grow from a single mesonephric duct to induce metanephric mesenchyme
Paramesonephric duct
Uterus
Vagina

FIG. 20.43 Embryologic schematic of the Weigert-Meyer rule, in which two ureteric buds grow from a single mesonephric duct to induce the metanephric mesenchyme. The ureters invert their positions as they fuse with the urogenital sinus. The upper-pole ureter crosses under the lower ureter and when ectopic can open into an abnormally low position such as draining into the vagina as illustrated. (Modified from Larsen WJ. *Human embryology.* New York, NY: Churchill Livingstone; 1997.)

Anomalous development of the WD may lead to an ectopic vas deferens. In certain clinical situations, the vas deferens is connected to the ureter rather than the verumontanum so that both the ureter and vas deferens drain into the prostatic urethra via a common duct. This situation may occur when the ureteric bud arises too high on the mesonephric duct and the subsequent common excretory duct becomes too long, resulting in incomplete absorption into the developing bladder (Schwarz and Stephens, 1978). This anomaly, although extremely rare, should be kept in mind when evaluating males with recurrent epididymitis and ipsilateral hydroureteronephrosis.

Development of the Ureter

At approximately 5 weeks' gestation, the stalk of the ureteric bud elongates to become the ureter. Morphologically, the ureter begins as a simple epithelial tube lined with cuboidal cells and surrounded by loose mesenchyme. The epithelium attains transitional differentiation by 14 weeks, whereas urine production has already started at approximately 12 weeks' gestation. The first signs of ureteral muscularization and development of elastic fibers are seen at 12 weeks' gestation. Smooth muscle differentiation is first detected in the subserosal region of the bladder dome and extends toward the bladder base and urethra, whereas smooth muscle differentiation in the ureter occurs later within the subepithelial region of the ureterovesical junction, ascending toward the intrarenal collecting system (Baker and Gomez, 1998). During embryonic ureteral and bladder development, epithelial-mesenchymal interactions are necessary for the induction of smooth muscle (Baskin et al., 1996a; Fig. 20.44). The sonic hedgehog (Shh) pathway is thought to be the key molecular pathway with the Shh expressing urothelium necessary for induction of bladder smooth muscle (Cao et al., 2010). Interestingly, smooth muscle differentiation occurs in subserosal bladder mesenchyme, implying a concentration gradient with higher levels of Shh inhibiting smooth muscle differentiation near the epithelium and lower levels inducing smooth muscle differentiation in more distant positions.

Smooth muscle

FIG. 20.44 Bladder smooth muscle differentiation is dependent on signaling from the urothelium to the bladder mesenchyme through the Sonic Hedgehog pathway. (Modified from Baskin LS, Hayward SW, Young P, Cunha GR. Role of mesenchymal-epithelial interactions in normal bladder development. *J Urol.* 1996;156(5):1820–1827.)

A number of genes have been implicated in congenital ureteral anomalies (Table 20.4). A mutation of the *PAX2* gene has been identified in a human family carrying renal coloboma syndrome, a rare autosomal dominant syndrome characterized by optic nerve coloboma, renal anomalies, and vesicoureteral reflux (Sanyanusin et al., 1996). *EYA1* is mutated in patients with the dominantly inherited disorder, branchio-oto-renal syndrome, which includes a duplex collecting system, renal hypoplasia and dysplasia, and renal agenesis (Abdelhak et al., 1997a). Pax2 is required for the growth and elongation of the mesonephric ducts before ureteric bud formation, whereas Eya1 appears to regulate the GDNF expression, which is a prerequisite for ureteric bud outgrowth. Bmp4 and FoxC1 appear to play a suppressive role in the ureteric bud outgrowth. Evidence suggests that BMPs control formation of smooth muscle in the proximal ureter and pelvis (Haraguchi et al., 2012). BMP4, expressed in the caudal mesenchyme cells, induces ureteral morphogenesis including smooth muscle and urothelial differentiation (Brenner-Anantharam et al., 2007). Consistent with such a role, *Bmp4*- and *Bmp5*-mutant mice display hydronephrosis and hydroureter (Miyazaki et al., 2003).

TABLE 20.4

Clinical Correlation: Selected Gene Mutations Associated With CAKUT Syndromes

SYNDROME	GENE	INHERITANCE	RENAL PHENOTYPES
Alagille	*JAG1* (Notch signaling pathway)	Autosomal Dominant	Agenesis, hypoplasia, cystic dysplasia, UPJ obstruction, VUR
Aniridia-Wilms tumor (WAGR)	*WT1*	Autosomal Dominant	Tumor, nephromegaly
ATR-X	*ATRX*	X-linked	Hypoplasia, agenesis, VUR, hydronephrosis
Branchio-oto-renal	*EYA1*, *SIX1*	Autosomal Dominant	Hypoplasia, VUR
Caudal regression	*VANGL1*	Autosomal Dominant Autosomal Recessive	Agenesis, ectopic kidney, hypoplasia, hydronephrosis, VUR
CHARGE	*CHD7*	Autosomal	Agenesis, hypodysplasia,

		Dominant	hydronephrosis, hydroureter
Cornelia de Lange	*NIPBL*	Autosomal Dominant	Hypoplasia, VUR, pelvic dilation, renal ectopia
Fraser	*FRAS1*, *FREM2*	Autosomal Recessive	Renal agenesis, cystic dysplasia, hypoplasia, hydronephrosis, bladder agenesis
Hypoparathyroidism-deafness-renal	*GATA3*	Autosomal Dominant	Agenesis, hypodysplasia, VUR
Kallmann	*KAL1*, *KAL2*	X-linked or Autosomal Dominant	Unilateral renal agenesis, VUR, cystic dysplasia
Maturity-onset diabetes of the young type V	*HNF1*	Autosomal Dominant	Cystic dysplasia, hypoplasia, glomerulocystic disease, agenesis, oligomeganephronia
Meckel-Gruber	*MKS1–4*	Autosomal Recessive	Cystic dysplasia, hypoplasia
Noonan	*NS1*	Autosomal Dominant	Cystic dysplasia, duplication, hydronephrosis
Okihiro (aero-renal-ocular)	*SALL4*	Autosomal Dominant	Pelvic or horseshoe kidney, hypoplasia, VUR
Pallister-Hall	*GL/3* (Sonic hedgehog signaling pathway)	Autosomal Dominant	Agenesis, hydronephrosis, hydroureter, renal ectopia, horseshoe kidney
Renal coloboma	*PAX2*	Autosomal Dominant	Hypoplasia, VUR, UPJ obstruction
Renal-hepatic-pancreatic dysplasia	*EVC, EVC2*	Autosomal Recessive	Cystic dysplasia
Rubinstein-Taybi	*CBP EP300*	Autosomal Dominant	Unilateral agenesis, cystic hypodysplasia, urethral defects
Roberts	*ESC02*	Autosomal Recessive	Agenesis, hypodysplasia, hydronephrosis
Silverman (dyssegmental dwarfism)	*HSPG2*	Uncertain	Hydronephrosis
Simpson-Golabi-Behmel	*GPC-3*	X-linked	Medullary cystic dysplasia
Smith-Lemli-Opitz	*DHCR7*	Autosomal	UPJ obstruction,

		Recessive	hydronephrosis, VUR, cystic dysplasia
Townes-Brocks	*SALL1*	Autosomal Dominant	Agenesis, hypoplasia, PUV, VUR, meatal stenosis
Zellweger	*PEX*	Autosomal Recessive	Cystic dysplasia, hydronephrosis

Development of the Bladder and Continence Mechanism

By the 10th week of gestation, the human bladder is a cylindrical tube lined by a single layer of cuboidal cells surrounded by loose mesenchymal tissue. The allantois becomes the urachus that connects the fetal bladder to the yolk sac, which is rudimentary in humans and probably nonfunctional. The apex of the bladder ultimately tapers as the urachus, and by the 12th week the urachus involutes to become a fibrous cord, the *median umbilical ligament.* The bladder epithelium consists of bilayered cuboidal cells between the 7th and 12th weeks and acquires mature urothelial characteristics between weeks 13 and 17. By the 21st week, bladder epithelium becomes four to five cell layers thick and demonstrates ultrastructural features similar to fully differentiated urothelium. Between the 7th and 12th weeks, the surrounding connective tissues condense, and smooth muscle fibers begin to appear, first at the region of the bladder dome and later proceeding toward the bladder base. Collagen fibers first appear in the lamina propria and then later extend into the deeper fibromuscular wall between the muscle fibers (Newman and Antonakopoulos, 1989).

Bladder compliance is thought to change during development. When studied in whole-organ preparations of fetal sheep bladders, bladder compliance is very low during early gestation and increases gradually thereafter (Coplen et al., 1994). The mechanism of these changes in bladder compliance may involve alterations in both smooth muscle tone and connective tissue composition. This phenomenon is also observed in developing human bladders (Kim et al., 1991). During gestation, bladder wall musculature increases in thickness and relative collagen content decreases. The ratio of thick-to-thin collagen fibers also decreases, whereas the amount of elastic fibers increases. These changes in compliance seem to coincide with the time of fetal urine production at approximately 10 weeks' gestation, suggesting a possible role for mechanical distention (Baskin et al., 1994). In organ cultures of fetal mouse bladders, distention promoted a more orderly development of collagen fiber bundles within the lamina propria in comparison with decompressed bladder explants, suggesting that mechanical factors from accumulating urine may play a role during bladder development (Beauboeuf et al., 1998).

No functional study has been done to assess human fetal continence mechanisms. Only a handful of ontogenic descriptions are available using human fetal specimens, providing a basis for speculative theories (Tanagho and Meyers, 1969; Yucel and Baskin, 2004). A mesenchymal condensation forms around the caudal end of the UGS after division of the cloaca and rupture of the cloacal membrane. Striated muscle fibers can be seen clearly by the 15th week. At this time, the smooth muscle layer becomes thicker at the level of bladder neck and forms the inner part of the urethral sphincter, which is composed of smooth muscle fibers centrally and striated muscle fibers peripherally (Bourdelat et al., 1992). Subsequently, sexual dimorphism comes into play with the formation of the prostate gland in males and the vagina in females (Tichy, 1989). The urethral sphincter muscle fibers extend posteriorly, projecting to the lateral wall of the prostate or to the lateral wall of the vagina.

Clinical Correlation: Vesico-ureteral Reflux

Vesicoureteral reflux occurs in 1 : 500 to 1 : 1000 births. The majority of vesicoureteral reflux is of no clinical consequence. More severe reflux in the setting of urinary tract infection is a risk factor for pyelonephritis (RIVUR Trial Investigators et al., 2014). The mechanism of reflux is a relatively short intramural ureteral tunnel that lacks sufficient muscle to facilitate the normal unidirectional passage of urine from the kidneys into the bladder. During normal bladder growth, ureteral valves often gain additional musculature, hence the high rate of spontaneous resolution of moderate and low grades of vesicoureteral reflux (Tanagho and Hutch, 1965). **In higher grades of reflux, the abnormal ureteral bud inappropriately signals the metanephric mesenchyme leading to renal dysplasia with reflux most likely an associated but noncausal phenomenon** (Mackie and Stephens, 1977).

Clinical Correlation: Bladder Exstrophy

Bladder exstrophy occurs in approximately 1 : 30.000 live births, with cloacal exstrophy being even less common at approximately 1 : 300,000 newborns (1987). Exstrophy of the bladder is characterized by a lower abdominal wall defect and separation of the pubic symphysis in which the anterior aspect of the bladder is open to the environment along with an open prostatic urethra and dorsal aspect of the penis (epispadias; Beaudoin et al., 1997). The trigone of the bladder and verumontanum in the prostate are visible on physical examination and the hemicorporal bodies. Embryologically, exstrophy of the bladder is caused by incomplete closure of the inferior aspect of the anterior abdominal wall and anterior bladder wall. Exstrophy of the bladder is thought to be secondary to failure of mesechymal cells to migrate between the ectoderm of the abdomen and endoderm of the cloaca during the fourth week of gestation. This results in absence of the inferior parts of the rectus abdominis muscle, external and internal oblique muscles, and transverse abdominis muscles. The thin epidermis and anterior wall of the bladder rupture, causing an open anterior bladder wall defect (Ambrose and O'Brien, 1974).

Clinical Correlation: Urachal Anomalies

In the adult, the urachus becomes a thick fibrous cord called the *median umbilical ligament*. If any remnant of the urachal lumen persists, anomalies of the urachus can occur such as a cyst (which often presents with infection), sinus (patency with the bladder), or fistula (complete patency with urine draining from the umbilicus). Treatment consists of excising retained patent structures (Mesrobian et al., 1997). Prophylactic excision of an incidentally found urachal anomaly does not appear warranted because the risk for malignancy later in life is remote and a large number of urachal anomalies would need to be removed to prevent a single case of urachal adenocarcinoma (Gleason et al., 2015).

Clinical Correlation: Duplication Anomalies

The ureter arises during the fourth week of embryonic development from the mesonephric, or Wolffian, duct. In ureteral duplication, the ureteric bud divides into two ureters resulting in two separate collecting systems for the kidney (Tanagho, 1976). This occurs in approximately 1% of the population, and most of the time the ureteral duplication is of no clinical consequence with both ureters either entering the bladder in their normal position in the trigone or connecting outside the bladder, the so-called *Y duplication*. **Ureteral**

duplication can be an issue when the upper-pole ureter does not insert into the bladder but instead into an ectopic site (see later) or the upper-pole ureter is blocked by a diverticulum within the bladder, a so-called *ureterocele* (see later).

Clinical Correlation: Ectopic Ureter

An ectopic ureter is defined as opening anywhere except into the trigone of the urinary bladder. In males, an ectopic ureter usually inserts into bladder neck or prostatic urethra but may also may insert into the vas deferens or seminal vesicle. In females, an ectopic ureter may insert into the bladder neck, the urethra, or the Gartner's duct and vaginal vestibule. In the latter two cases, these girls may present with persistent incontinence (Williams, 1954). Embryologically, an ectopic ureter results from the ureter not being incorporated into the posterior part of the urinary bladder. Instead it is carried caudally with the mesonephric duct and is incorporated into the caudal portion of the UGS. The caudal portion of the UGS becomes the prostatic urethra in males and the vagina in females, hence the explanation for the typical location of ectopic ureters.

Clinical Correlation: Ureterocele

Ureteroceles are saclike structures or diverticula of the distal ureter that can obstruct the flow of urine from the kidney to the bladder (Tanagho, 1972; Coplen and Duckett, 1995). They are most common in duplex systems affecting the upper-pole ureter but can also occur in single systems. It is possible that ureteroceles are a continuum with ectopic ureters, with pseudo-ureterocele being in between. The embryologic explanation of a ureterocele is controversial but thought to be secondary to a transient obstruction (Tanagho, 1972).

Key Points: Bladder/Ureteral Development

- The bladder and urethra develop from the endodermal urogenital sinus, which derives from the ventral portion of the cloaca after it becomes subdivided by the urorectal septum.
- Cell lineage studies have shown that the fibromusculature wall of the trigone is formed from bladder smooth muscle cells with only a minor

contribution from ureteric smooth muscle.

- According to the Weigert and Meyer rule, the upper-pole ureteral orifice rotates dorsally relative to the lower-pole orifice and assumes a more caudal and medial position with less chance of reflux.
- Ureteral duplication can be an issue when the upper-pole ureter does not insert into the bladder but instead in an ectopic site, or the upper-pole ureter is blocked by a diverticulum within the bladder, a so-called *ureterocele*.
- In females, ectopic ureters may insert into the bladder neck, urethra, or vaginal vestibule. In the latter two cases, these girls may present with persistent incontinence.

Kidneys

The kidneys develop in identical fashion regardless of sex (Fig. 20.45). Fetal lobulations are prominent as development progresses (Fig. 20.46). Note the increase in length and width of the fetal kidneys over time. The kidney shows a bifid ureter at 14 weeks' gestation, a variation of normal development in which the upper and lower poles have separate ureters that connect into a single ureter, in this case at the lower pole of the kidney (Moore et al., 2016). In humans, multiple normal variations of normal ureteral development have been described with bifid ureters as seen in Fig. 20.45 and complete ureteral duplication.

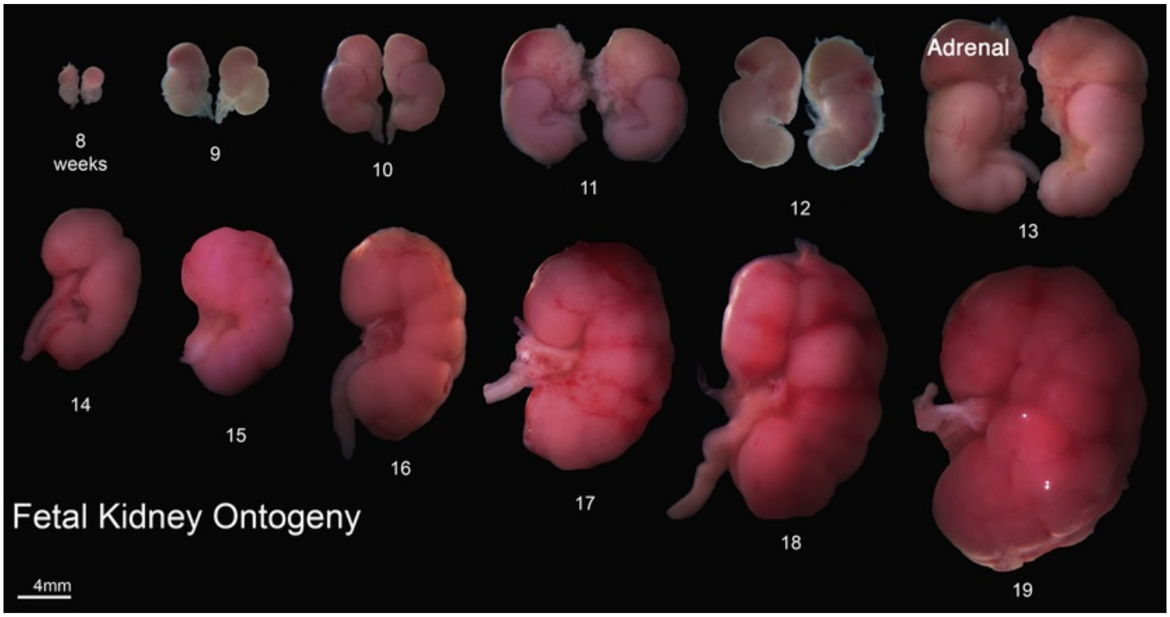

FIG. 20.45 Whole-mount photographs of human fetal kidneys (8 to 19 weeks' gestation). Note the progressive increase in renal size over time and well-visualized fetal lobulations (starting at 12 weeks' gestation). The adrenal gland can be seen capping the upper pole of the fetal kidney in the 8- to 13-week specimens. Relative sizes of specimens are not exact, but increase with age.

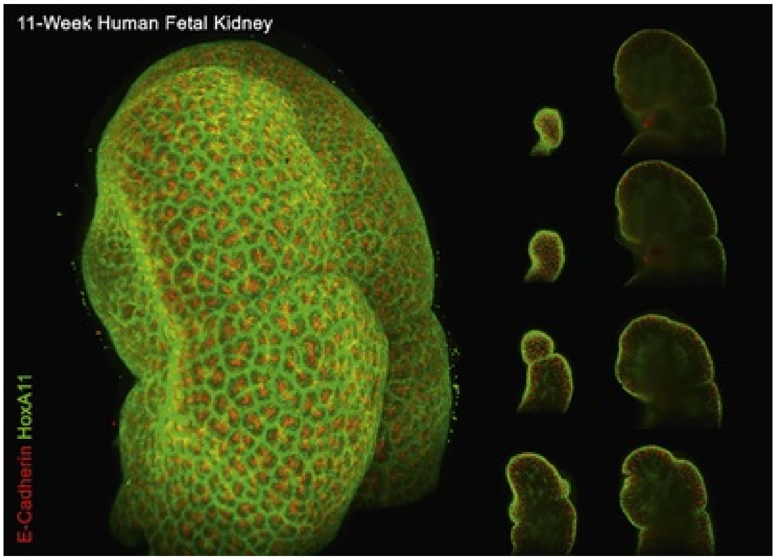

FIG. 20.46 An 11-week human fetal kidney stained for metanephric mesenchyme-expressed HoxA11 *(green)* and E-cadherin *(red)* imaged using lightsheet fluorescence microscopy. Individual optical sections *(left)* are reconstructed into full three-dimensional volume *(right).*

Early Events in Kidney Development

Mammals develop three sets of kidneys in the course of intrauterine life (Fanos et al., 2015; Moore et al., 2016; Pietila and Vainio, 2014; Ryan et al., 2018). **The embryonic kidneys are, in order of their appearance, the *pronephros*, the *mesonephros*, and the *metanephros*.** The first two kidneys regress completely (pronephros) or partially (mesonephros) in utero, and the third becomes the permanent kidney. **Embryologically, all three kidneys develop from the intermediate mesoderm.** As the notochord and neural tube develop, the mesoderm located on either side of the midline segregates into three subdivisions: *paraxial (somites)*, *intermediate*, and *lateral plate mesoderm*. As the embryo undergoes transverse folding, the intermediate mesoderm separates from the paraxial mesoderm and migrates ventrally to the dorsal wall of the intraembryonic coelom (the future abdominal cavity). At this time, there is a progressive craniocaudal development of the bilateral longitudinal mesodermal masses, called *nephrogenic* cords. Each cord bulges from the posterior wall of the coelomic cavity, producing the paired urogenital ridges. The gonadal ridge, discussed earlier, is located on the medial aspect of the urogenital ridge.

Pronephros and Mesonephros

The mammalian *pronephros* is a transitory, nonfunctional kidney analogous to that of primitive fish. In humans, the first evidence of the pronephros is seen late in the third week, and it completely degenerates by the start of the fifth week. Development of the pronephric tubules/vesicles starts at the cranial end of the nephrogenic cord in the thoracic region and progresses caudally. This craniocaudal wave of pronephric tubule/vesicle formation is followed immediately by craniocaudal degeneration of the pronephric tubules (Fig. 20.47A). Formation of pronephric tubule/vesicle formation involves a mesenchymal-to-epithelial conversion. The significance of the pronephros is the generation of the pronephric duct that grows caudally within the urogenital ridge. As the pronephric tubules degenerate, the retained pronephric duct becomes the mesonephric duct as it grows caudally into the domain of mesonephric tubule development. This simply involves a name change.

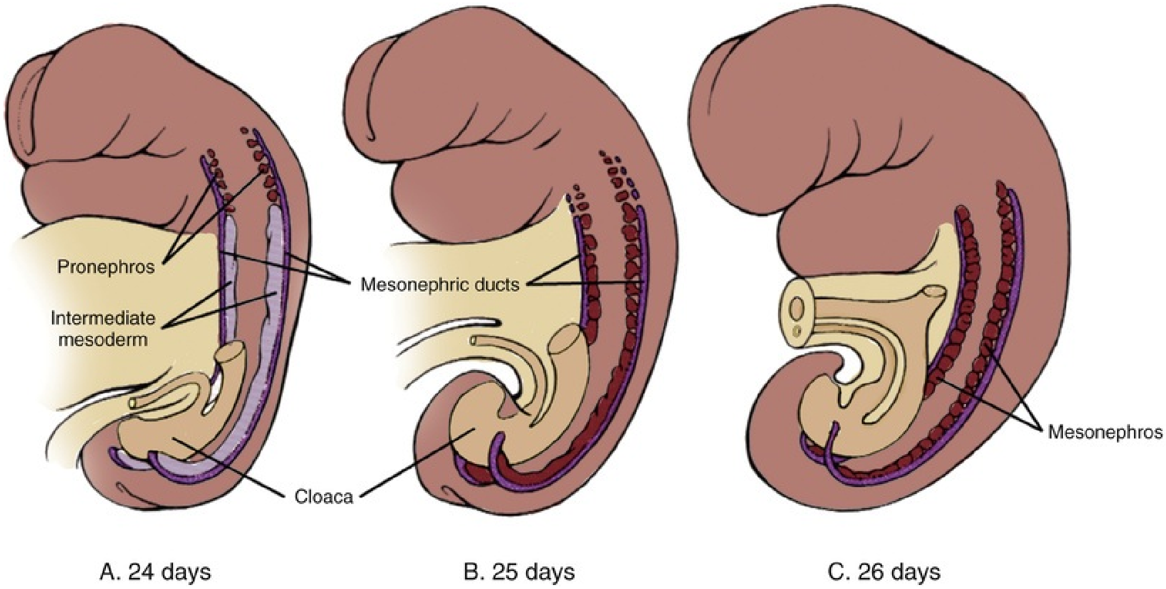

FIG. 20.47 Development of pronephros and mesonephros. (A) Pronephros develops in each of five to seven cervical segments, but this primitive renal structure degenerates quickly during the fourth week. The mesonephric ducts first appear on day 24. (B and C) Mesonephric vesicles and tubules form in a craniocaudal direction throughout the thoracic and lumbar regions. The cranial pairs degenerate as caudal pairs develop, and the definitive mesonephros contains about 20 pairs confined to the first three lumbar segments. (Modified from Larsen WJ. *Human embryology.* New York, NY: Churchill Livingstone; 1997.)

The second kidney, the *metanephros,* is also transient, but in higher vertebrates the metanephros serves as an excretory organ for the embryo while the definitive kidney, the *metanephros*, begins its development (see Fig. 20.47BC). As the bilateral *mesonephric ducts* (also called *Wolffian ducts*) extend caudally into the mesonephric mesenchyme within the urogenital ridge, mesonephric tubules are induced that join the paired mesonephric ducts. In total, approximately 40 mesonephric tubules form (see Fig. 20.31). The mesonephric (Wolffian) ducts extend caudally and eventually terminate by joining with the epithelium of the cloaca.

Formation of mesonephric tubules begins in the fourth week and involves the condensation of mesenchyme to form dense aggregates that in turn convert into epithelial vesicles. These vesicles subsequently elongate to form tortuous (initially *S*-shaped) tubules that join the mesonephric ducts. The formation of mesonephric tubules progresses from cranial to caudal and results in the formation of approximately 40 pairs of mesonephric tubules. Only a maximum of approximately 30 pairs of mesonephric tubules are seen at any one time as cranially tubules start to degenerate starting at about the fifth week before the most caudal tubules form (see Fig. 20.31). By the fourth month, the human mesonephros has degenerated, except for a few elements that persist into maturity as part of the male reproductive tract. In males, some of the cranially located mesonephric tubules become the efferent ducts of the testes. The paradidymis consists of retained mesonephric tubules near the head of the epididymis. In females, remnants of cranial and caudal mesonephric tubules form small, nonfunctional epithelial cysts residing within the broad ligament of the uterus, termed the *epoöphoron* and *paroöphoron* (see Table 20.3). As discussed earlier, residual segments of the mesonephric (Wolffian) duct are frequently found within the fibromuscular wall of the vagina.

Metanephros

The definitive kidney, or the *metanephros*, initially forms in the sacral region as *ureteric buds* sprout from the caudal portion of the mesonephric duct and come in contact with condensing *(metanephric mesenchyme)* at about the 4 weeks' gestation (Fig. 20.48). The ureteric bud elongates cranially into the metanephric mesenchyme and begins to branch dichotomously. The tip of the branching ureteric bud, called the *ampulla,* induces the metanephric mesenchyme to condense and to convert into epithelial vesicles. As the ureteric bud divides and branches, each new ampulla acquires a caplike condensation of metanephric mesenchyme that undergoes a mesenchymal-to-epithelial transition (see Fig.

20.45).

FIG. 20.48 Development of the metanephros (kidney). (A) Key factors in kidney development involve interplay between secreted signals and transcription factors both in the ureteral bud *(UB)* that is derived from the Wolffian duct *(WD)* and the kidney metanephric mesenchyme *(MM).* (B) The ureteral bud enters the kidney mesenchyme and makes the first *t*-type branch. At the same time, the ureteral bud induces the condensation of metanephric mesenchyme cells to form a cap of mesenchyme. Cap metanephric mesenchyme cells contain the progenitors/stem cells of the nephrons. (C) The sequential and reciprocal tissue interactions between the ureteral bud and the metanephric mesenchyme advance kidney morphogenesis–inducing nephrons. (D) The nephron becomes segmented into the glomerulus, proximal tubules, loop of Henle, distal tubule, connecting tubule, and collecting duct. The collecting duct drains the concentrated urine to the renal pelvis and from there via the ureter to the bladder. (Modified from Pietila I, Vainio SJ. Kidney development: an overview. *Nephron Exp Nephrol.* 2014;126[2]:40.)

The ureteric bud and metanephric mesenchyme exert reciprocal inductive effects on each other, and proper differentiation of these primordial structures depends on these reciprocal inductive signals (Fanos et al., 2015; McMahon, 2016; Pietila and Vainio, 2014; Reidy and Rosenblum, 2009; Uy and Reidy, 2016). **The metanephric mesenchyme induces the ureteric bud to elongate**

and branch (Cebrian et al., 2004), **and in turn the ureteric bud induces the metanephric mesenchyme to condense and undergo mesenchymal-epithelial conversion to form metaphoric tubules that will differentiate into nephrons.** The initially induced epithelial vesicles elongate and in turn form *S*-shaped structures, and further growth and elongation generates the complex elements of the nephron (the glomerulus, proximal convoluted tubule, loop of Henle, and distal convoluted tubule), all of which are derived from the metanephric mesenchyme. The urine collecting system, consisting of collecting ducts, calyces, pelvis, and ureter, is formed from the ureteric bud (see Fig. 20.48). Urine production by the metanephric kidney begins in the 10th week of gestation.

All metanephric nephrons are formed in the same way, and the overall process involves fairly well-defined developmental stages (Larson et al., 1983; Saxen and Sariola, 1987). The metanephric mesenchyme first condenses to form a four- to five-cell layered dense mesenchymal condensate around the ampulla of the advancing ureteric bud. Near the interface of the ampulla and its adjacent ureteric branch, a cluster of cells separates from a mesenchymal condensate and forms an oval mass called a *pretubular aggregate that undergoes mesenchymal-to-epithelial conversion.* An internal cavity forms within the epithelializing pretubular aggregate, at which point the structure is called the epithelial *renal vesicle* (stage I). Cells of the stage I renal vesicles are tall columnar and are stabilized by attachment to a newly formed basement membrane. The *renal vesicles* elongate to form a comma-shaped body that is in turn converted to an *S*-shaped body, one end of which establishes connection with the distal tip of a ureteric branch. Multipotential precursors residing within renal vesicles ultimately give rise to all epithelial cell types of the nephron (Herzlinger et al., 1992). Nephron segmentation into glomerular and tubular domains is initiated by the sequential formation of two clefts within the renal vesicle (stage II; upper and lower clefts). Creation of a lower cleft, termed the *vascular cleft*, precedes formation of a comma-shaped body. Generation of an upper cleft in the comma-shaped body precedes formation of an *S*-shaped body. At this stage, the cup-shaped glomerular capsule is recognized in the lowest limb of the *S*-shaped tubule. Epithelial cells lining the inner wall of this cup will compose the visceral glomerular epithelium, or podocyte layer. Cells lining the outer wall of the cup will form parietal glomerular epithelium, which lines the Bowman capsule. The glomerular capillary tuft is formed via recruitment and proliferation of endothelial and mesangial cell precursors. The rest of the *S*-shaped tubule develops into the proximal convoluted tubule, the loop of Henle, and the distal convoluted tubule. When the cup-shaped glomerular capsule matures into an oval structure, the nephron has now passed into stage III of development. Now the nephron can be divided into identifiable proximal and distal convoluted tubules. The stage IV nephron is characterized by a round glomerulus that closely resembles the mature renal corpuscle. The morphology of the proximal convoluted tubule resembles that of a mature nephron, whereas the distal segments are still primitive. In humans, all nephrons at birth are in varying steps of stage IV. Mesenchymal cells that do not become tubular epithelium give rise to interstitial stromal cells, which differentiate into a diverse population including fibroblasts, lymphocyte-like cells, and pericytes. Overall, these events are reiterated throughout the growing kidney so that older, more differentiated nephrons are located in the inner part of the kidney near the juxtamedullary region and newer, less differentiated nephrons are found at the cortex. In humans, although renal maturation continues to take place postnatally, nephrogenesis is essentially complete before birth at around 32 to 34 weeks' gestation (Pietila and Vainio, 2014; McMahon, 2016).

Collecting System

The dichotomous branching of the ureteric bud determines the eventual pelvicalyceal patterns and their corresponding renal lobules (Cebrian et al., 2004; see Fig. 20.48). In humans, the first nine branch generations are formed by approximately 15 weeks' gestation. By 20 to 22 weeks, ureteric bud branching is completed. Thereafter, collecting duct development occurs by extension of peripheral branch segments. Between 22 and 24 weeks' fetal gestation in humans, the peripheral (cortical) and central (medullary) domains of the developing kidney are established. The renal cortex, which represents 70% of total kidney volume at birth, becomes organized as a relatively compact, circumferential rim of tissue on the periphery of the kidney. The renal medulla, which represents 30% of total kidney volume at birth, has a modified cone shape with a broad base contiguous with cortical tissue. The apex of the cone is formed by convergence of collecting ducts in the inner medulla to form the *renal pyramids and papilla that project into the minor calyces.* Two to three minor calyces converge to form three to four major calyces that in turn empty into the renal pelvis. Distinct morphologic differences emerge between collecting ducts located in the medulla compared with those located in the renal cortex.

Medullary collecting ducts are organized into elongated linear arrays that converge centrally in a region devoid of glomeruli. In contrast, collecting ducts located in the renal cortex continue to branch and induce metanephric mesenchyme. The most central segments of the collecting system, formed from the first five generations of ureteric bud branching, undergo remodeling by increased growth and dilation of these tubules to form the calyces and renal pelvis.

Molecular Mechanisms of Kidney Development

The details of inductive interactions among metanephric mesenchyme, the branching ureteric bud, and more recently the stroma are becoming clearer and provide insight into the complex regulatory mechanisms underlying renal development (Bekheirnia et al., 2017; Capone et al., 2017; Uy and Reidy, 2016). Formation of renal tubules and the collecting system occurs sequentially and requires dynamic interactions among epithelial, mesenchymal, and stromal cells. Many of the early events in embryonic kidney development were first elucidated by manipulating lower vertebrate embryos and by using an in vitro organ culture system. Grobstein's pioneering work in the 1950s led to an organ culture technique (Grobstein, 1956) whereby the metanephric mesenchyme is separated from the ureteric bud during the early part of kidney development and grown in vitro on a filter. An inducer tissue, such as ureter or spinal cord, cultured on the opposite side of the filter provided the inductive signal. This ingenious experimental approach has established the kidney as a model system for studying the role of epithelial-mesenchymal interaction in organogenesis. **The development of many other organs, including lung, salivary glands, mammary glands, gonads, prostate, and bladder, also require epithelial-mesenchymal interactions for the controlled differentiation and proliferation of tissues** (Baskin et al., 1996a; Cunha, 1985).

Formation of Nephric Ducts

The first recognizable event in renal development is formation of pronephric ducts within the intermediate mesoderm. The early intermediate mesoderm destined to become nephric ducts is distinguished by expression of the transcription factors LIM1, PAX2, and SIM1, but only LIM1 appears to be absolutely essential for nephric duct formation (Shawlot and Behringer, 1995).

PAX2 may be important for maintaining other marker gene expression in the nephric ducts (Torres et al., 1995). Available data suggest a model in which few opposing secreted factors from the surrounding tissues cumulatively restrict LIM1 expression to the intermediate mesoderm. LIM1 then activates PAX2 expression to further orchestrate the formation of nephric ducts.

Ureteric Bud Outgrowth Into Metanephric Mesenchyme

The outgrowth of the ureteric bud from the mesonephric duct and its invasion into the condensing blastema of metanephric mesenchyme is a crucial initiating event in the development of the adult kidney *(metanephros)*. Many candidate genes have been identified to play a critical role in this process (Brunskill et al., 2008; McMahon, 2016; Pietila and Vainio, 2014). In particular, several lines of evidence have revealed a crucial role of the RET-GDNF-GFRα1 pathway in the ureteric bud outgrowth. Glial cell line–derived neurotrophic factor (GDNF) is a secreted peptide expressed in the metanephric mesenchyme that activates the RET receptor, which is expressed in the mesonephric duct. GDNF activation of RET requires the glycosylphosphatidylinositol (GPI)-linked protein GFRα1, which is expressed in both metanephric mesenchyme and the mesonephric duct (see Fig. 20.48). Gene knockout mutations in *Ret, GDNF* (Moore et al., 1996; Pichel et al., 1996; Pietila and Vainio, 2014), and *GFRα1* (Cacalano et al., 1998) inhibit ureteric bud outgrowth. In organ culture systems, recombinant GDNF is sufficient to induce ectopic ureteric bud outgrowth (Sainio et al., 1997). However, the competence of the mesonephric duct to respond to GDNF is restricted along its anteroposterior axis. This anteroposterior restriction might be mediated by suppressors of RET signaling within the surrounding tissue, such as bone morphogenetic protein-4 (BMP4). In organ culture, BMP4 can suppress the activity of GDNF to induce ectopic ureteric bud formation (Brophy et al., 2001). Proper location of ureteric bud formation is also controlled by the localized expression of GDNF within the metanephric mesenchyme. Both positive and negative regulators have been described for GDNF localization. Homozygous mutation of transcription factor Eya1 causes failure of ureteric bud outgrowth and a resultant lack of GDNF expression in metanephric mesenchyme, suggesting that Eya1 regulates GDNF expression (Xu et al., 1999). In humans, haploinsufficiency of Eya1 results in a dominantly inherited disorder called *branchio-oto-renal syndrome,* which involves kidney and urinary tract anomalies

(Abdelhak et al., 1997b; Brophy et al., 2001). Expression of PAX2 in the metanephric mesenchyme is also required for GDNF activation (Brophy et al., 2001). GDNF expression is also suppressed at the anterior boundary of the metanephric mesenchyme through the concerted action of the FoxC1 and FoxC2 transcription factors (Kume et al., 2000). Mutations in either *Fox* gene result in an expansion of GDNF expression and the formation of ectopic ureteric buds. Most *FoxC1* homozygous mutants have duplex kidneys, in which the upper ureter is dilated and connects aberrantly to mesonephric duct derivatives in males such as seminal vesicles and vas deferens. In the developing kidneys, *Slit2* is primarily expressed in the mesonephric duct, whereas *Robo2* is expressed in the metanephric mesenchyme (Piper et al., 2000). Mice deficient in *Slit2* or *Robo2* exhibit ectopic ureteric bud formation, multiple ureters and hydroureter, and anterior expansion of GDNF expression (Grieshammer et al., 2004). SPRY1 negatively regulates GDNF-RET signaling. Loss of *Spry1* function in mice results in renal malformations, including multiple ureters, duplex kidneys and hydroureter, and increased expression of GDNF in the metanephric mesenchyme (Basson et al., 2006). The data therefore suggest that multiple factors regulate, both positively and negatively, the precise timing and localization of GDNF, which then functions as a guidance cue to activate RET, which is required for proper development and patterning of the metanephric kidney.

In humans (and mice), congenital anomalies of the kidney and urinary tract (CAKUT) are associated with mutations in these transcription factors and signaling pathways that are required for normal nephron differentiation (Takasato and Little, 2015; Uy and Reidy, 2016; Marciano, 2017). For example, multiple transcription factors (including Hox11, Eya1, Pax2, Six1, Six2, Osr1, and Sall1) regulate the balance between differentiation and maintenance of the nephron progenitors. Wnt signaling is also required for differentiation into the renal vesicle. HNF1B and Notch signaling contribute to the specification of the proximal tubules and terminal nephron differentiation (Fig. 20.49).

FIG. 20.49 Congenital abnormalities of the kidney and urinary tract (CAKUT) are associated with mutations in transcription factors (including Hox11, Eya1, Pax2, Six1, Six2, Osr1, and Sall1) that regulate the balance between differentiation and maintenance of the nephron progenitors. Multiple gene pathways such as Wnt signaling are also required for differentiation into the renal vesicle. HNF1B and Notch signaling contribute to the specification of the proximal tubules and terminal nephron differentiation. (Modified from Uy N, Reidy K. Developmental genetics and congenital anomalies of the kidney and urinary tract. *J Pediatr Genet.* 2016;5[1]:51–60.)

Ureteric Bud Branching

Once the ureteric bud has contacted the metanephric mesenchyme, it undergoes a dichotomous branching morphogenesis (Cebrian et al., 2004; Costantini and Kopan, 2010). Many of the same factors that regulate the initial outgrowth of the ureteric bud also appear to be essential for the subsequent branching of the ureteric bud. Ureteric bud branching is positively regulated by genetic and nutritional factors. PAX2, a paired-box–type transcription factor that is mutated in humans with renal coloboma syndrome, is a positive regulator of ureteric bud branching. During renal development, *Pax2* is expressed in the mesonephric duct, ureteric bud, and metanephric mesenchymal aggregates induced by ureteric bud branch tips (see Fig. 20.48). Mice with a *Pax2* mutation exhibit decreased ureteric bud branching and renal hypoplasia (Porteous et al., 2000). Ureteric bud branching is also positively regulated by vitamin A and its retinoic acid receptor signaling, which promote Ret expression. Rarα and Rarβ2 are expressed in stromal cells surrounding Ret-expressing ureteric bud branch tips. Mice deficient in these receptors exhibit a decreased number of ureteric bud branches and diminished expression of Ret (Batourina et al., 2001). Certain markers such as Wnt11 might already be compartmentalized to opposing poles of the dilated ureteric bud tips, even before a morphologic branch point is evident (Pepicelli et al., 1997). In mice deficient for the homeobox gene *Emx2* (Miyamoto et al., 1997), ureteric bud outgrowth into the metanephric mesenchyme appears normal, but the leading edge of the ureteric bud never dilates and branching is suppressed. Thus, ureteric development is arrested before the first branching event, and the resulting metanephric mesenchyme does not express markers indicative of induction. Similarly, mice with mutation of *Sall1* exhibit developmental arrest just after ureteric bud outgrowth and before dilation of the leading edge of the ureteric bud (Nishinakamura et al., 2001). In normal murine embryos, *Sall1* is expressed in metanephric mesenchyme. Thus, *Sall1* might control mesenchyme-derived signals that are necessary for ureteric bud dilation and branch point determination. Clearly, the pattern of ureteric bud branching and the expression of ureteric bud–specific genes are influenced by the metanephric mesenchyme. Indeed, heterologous mesenchyme derived from lung primordia cannot change the pattern of ureteric bud branching to that of lung epithelia or induce the ureteric bud to express lung-specific genes (Lin et al., 2001). Studies have demonstrated that BMP/activin-like kinase-3 (ALK3) signaling negatively regulates early ureteric bud branching in vivo (Hartwig et al., 2008). The cell surface receptor ALK3 binds BMP2 and BMP4 with high affinity and is expressed in the mesonephric duct. Inactivation of ALK3 changes the pattern of primary ureteric bud branching from bifid to trifid and increases the number of first- and second-generation branches. These defects are associated with decreased formation of subsequent branch generations, resulting in a decreased complement of collecting ducts. These observations suggest that the pattern of early ureteric bud branching is a critical determinant of subsequent branching morphogenesis. **Thus, ureteric bud epithelial branching morphogenesis is controlled by both intrinsic and extrinsic factors working**

in concert to generate a kidney-specific branching pattern (see Table 20.4).

Tubulogenesis

Classic tissue recombination experiments focused almost exclusively on the relationship between metanephric mesenchymal cells and ureteric bud epithelial cells. It is now clear that at least three cell types are involved in the control of renal development: the ureteric bud tip cells, the condensed metanephrogenic mesenchymal cells, and the stromal or interstitial mesenchymal cells. Once induced by the ureteric bud, the metanephric mesenchyme patterns itself into at least two different cell populations, a tubular one and a stromal one. The tubular cell population is thought to derive from mesenchymal cells in direct contact with the ureteric bud ampulla (Stark et al., 1994; Torres et al., 1995; Vainio et al., 1989), whereas the stromal cell population surrounds the tubular cells (Hatini et al., 1996). Once the mesenchyme has been patterned, these cells in the tubular zone undergo morphogenesis to become renal tubular epithelial cells. There is evidence that this process is dependent not only on signals from the ureteric bud but also on signals from the mesenchyme itself. One of these autocrine signals may be Wnt4, whose expression is induced in cells of the tubular zone after interaction with the ureteric bud. In *Wnt4* gene knockout mice, the ureteric bud forms and invades the metanephric mesenchyme, but subsequent development of epithelial tubules is abolished (Stark et al., 1994). This suggests that two signals are essential for renal tubule formation—initial ureteric bud–derived signals activating Wnt4 expression in the metanephric mesenchyme and Wnt4 itself as a mesenchymal autocrine signal. Signals from the stromal cell population also contribute to tubule formation, because tubulogenesis is perturbed in *Bf2* gene knockout mice (Hatini et al., 1996). The discovery that Wnt4 acts as a downstream signal during the induction cascade leading to renal tubulogenesis leads to the question regarding the nature of the initial ureteric bud–derived signals. In vitro data suggest a role for FGF2 and other uncharacterized factors secreted by the ureteric bud (Karavanova et al., 1996). Candidate molecules that may cooperate with FGF2 are Wnt11 and BMP7 (Kispert et al., 1996; Vukicevic et al., 1996). Localization of RET protein to the ureteric bud tips is reinforced by both GDNF (Pepicelli et al., 1997) and signals emanating from surrounding stromal cells. For example, retinoic acid receptors are expressed in the stromal cells and are required for stromal cell–mediated signaling to maintain high levels of RET expression in the bud tips (Batourina et al., 2001; Mendelsohn et al., 1999). Consistent with the role of retinoic acid receptors in maintaining RET expression in the dividing ureteric bud, rats with vitamin A deficiency have smaller kidneys and fewer nephrons (Merlet-Benichou et al., 1999). The cellular cross-talk among stromal, mesenchymal, and ureteric bud cells is further highlighted by gain- and loss-of-function experiments involving FGFs and BMPs. *Fgf7*-null mutant mice have fewer branch points and correspondingly fewer nephrons, whereas ectopic FGF7 in organ culture can stimulate branching (Qiao et al., 1999a, 1999b). FGF1 and FGF10 affect elongation of the ureteric bud stalk before the branch-point decision is made (Qiao et al., 1999a). Null mutations in *Bmp7* are associated with even more severe phenotypic anomalies, exhibiting limited ureteric bud branching morphogenesis and complete renal developmental arrest. Yet it is difficult to assess how FGFs and BMPs exert their collective effects on branching given the interplay among all the cell types present in the early kidney (Dudley et al., 1999). In addition to the proteins just mentioned, a growing list of growth factors, secreted peptides, and their receptors have been implicated in the control of branching morphogenesis, most by using a variety of in vitro model systems (Pohl et al., 2000). For many of these factors, however, genetic studies have not proved conclusive in assigning specific functional roles during ureteric bud branching in vivo, either because of potential redundancies or embryonic lethalities before the onset of kidney development. Nevertheless, the role of these factors in renal development must be considered.

Mesenchymal-Epithelial Conversion

The inductive signals emanating from the ureteric bud promote condensation of the metanephric mesenchymal cells around the ureteric bud tips and subsequent tubulogenesis (Uy and Reidy, 2016). Mice with null mutations of *Pax2* or *Wt1* fail to exhibit ureteric bud outgrowth, and in both cases the metanephric mesenchyme does not respond to induction even when recombined with strong inducers in vitro (Brophy et al., 2001; Kreidberg et al., 1993). The establishment of glomerular versus tubular cell fates is dependent on negative feedback between *Wt1* and *Pax2* (Ryan et al., 1995). During early kidney development, the expression domain of *Pax2* is complementary to that of *Wt1* in *S*-shaped bodies. *Wt1* expression is restricted to glomerular epithelial precursors (Buckler et al., 1991), whereas *Pax2* expression is restricted to the portion that gives rise to tubular epithelial precursors of the proximal and distal nephron segments and later repressed in differentiated tubular epithelium (Dressler and Douglass, 1992). Evidence in support of Wnt proteins as mesenchyme inducers has been gained from in vitro induction assays using Wnt-expressing cell lines (Herzlinger et al., 1994; Kispert et al., 1998). Of the *Wnt* mutants examined to date, only *Wnt4*, which is expressed in the mesenchyme and not the ureteric bud, is crucial for propagation of the inductive signals. Although *Wnt4* mutant mesenchyme is able to aggregate in response to ureteric bud contact, these mutant aggregates do not form polarized epithelia. Rat ureteric bud cells secrete tubulogenic factors, such as leukocyte-inhibitory factor, which, together with FGF2, appears to stimulate growth and tubulogenesis in vitro (Plisov et al., 2001). Once induced to form aggregates, metanephric mesenchyme becomes polarized into an early renal vesicle. This vesicle is closely associated with the branching ureteric bud and will eventually connect to the ureteric bud epithelium to form a continuous tubule. Profound changes take place in the expression of cell adhesion molecules such as cadherins. Shortly after induction, metanephric mesenchyme expresses R-cadherin, cadherin-6, and E-cadherin, along with suppression of the mesenchyme-specific cadherin-11. Both R-cadherin and cadherin-6 mutants show defects in the rate of mesenchymal condensation and polarization (Dahl et al., 2002; Mah et al., 2000). Some renal vesicles in cadherin-6 mutants also fail to fuse to the ureteric bud epithelia, resulting in “dead-end” tubules and a subsequent loss of nephrons.

Renal Vascular Development

The origin of intrarenal vasculature is not completely understood. Until recently, it was thought that renal vasculature derived exclusively from branches off the aorta and other preexisting extrarenal vessels (“angiogenic” hypothesis). There is evidence, however, that the renal vessels may originate in situ, within the embryonic metanephric mesenchyme from vascular progenitor cells (“vasculogenic” hypothesis; Loughna et al., 1996; Tufro et al., 1999). Using antibodies to Flk-1, a vascular endothelial growth factor (VEGF) receptor present in angioblasts and mature endothelial cells, it was demonstrated that endothelial cell precursors were already present in the prevascular rodent metanephric mesenchyme before any vessels were discernible from a morphologic standpoint. When embryonic kidneys are cultured at the usual atmospheric oxygen concentration, vessels do not develop. However, if the explants are cultured in a hypoxic atmosphere containing 5% oxygen, capillary sprouts develop within and outside the glomeruli, an effect that is inhibited by anti-VEGF antibodies (Tufro-McReddie et al., 1997). Depending on the developmental potential of the cells involved, both angiogenesis and vasculogenesis may play a role in the development of renal vasculature (Abrahamson et al., 1998).

Clinical Correlation: Vascular Anomalies

As the kidneys migrate from their origin in the pelvis cranially into the upper lumbar region, they are vascularized by a succession of transient aortic sprouts that arise at progressively higher levels. These arteries do not elongate to follow the ascending kidneys but instead degenerate and are replaced by successive new arteries. The final pair of arteries forms in the upper lumbar region and becomes the definitive renal arteries. Occasionally, a more inferior pair of arteries persists as accessory lower-pole arteries. **These lower-pole arteries cross ventral to the ureter and can cause intermittent ureteropelvic junction obstruction requiring repositioning of the ureter behind the accessory lower-pole renal artery.** The common variation in blood supply to the kidney is a reflection of the continually changing embryonic renal vasculature. This is reflected in that 25% of adult kidneys have two or more renal arteries (Moore et al., 2016).

Clinical Correlation: Ascent Anomalies

Between the sixth and ninth weeks, the kidneys ascend to the upper lumbar region just below the adrenal glands (Fig. 20.50). The precise mechanism responsible for renal ascent is not known, but it is speculated that differential growth of the lumbar and sacral regions of the embryo plays a major role. When the kidney fails to ascend properly, its location becomes ectopic. If its ascent fails completely, it remains as a pelvic kidney. **The inferior poles of the kidneys may also fuse, forming a horseshoe kidney (incidence ~1 : 500) that crosses ventral to the aorta. During ascent, the fused lower pole is arrested by the inferior mesenteric artery and thus does not reach its normal site.** Typically, the horseshoe kidney produces no symptoms but can be associated with a slight increase in ureteropelvic-junction obstruction and renal calculi. Rarely, the kidney fuses to the contralateral one and ascends to the opposite side, resulting in a cross-fused ectopy.

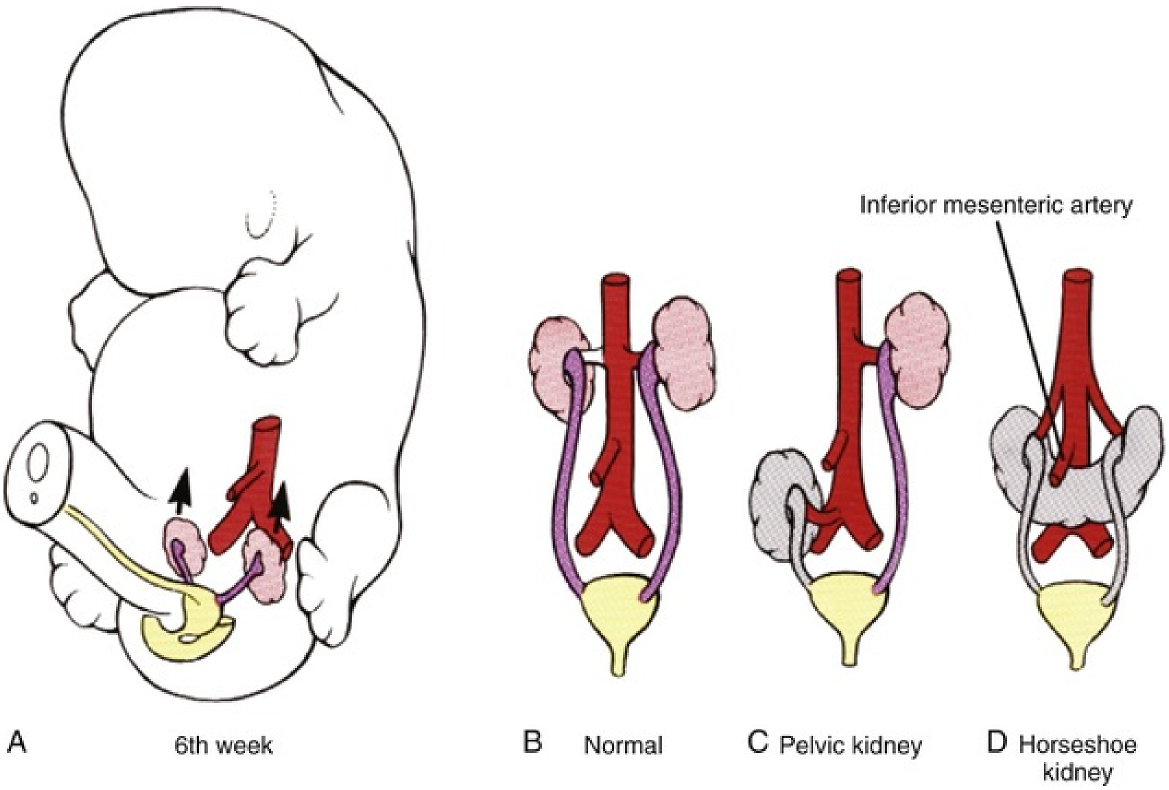

FIG. 20.50 Normal and abnormal ascent of the kidneys. (A and B) The metanephros normally ascends from the sacral region to its definitive lumbar location between the sixth and ninth weeks. (C) Rarely, a kidney may fail to ascend, resulting in a pelvic kidney. (D) If the inferior poles of the kidneys fuse before ascent, the resulting horseshoe kidney does not ascend to a normal position because of entrapment by the inferior mesenteric artery. (Modified from Larsen WJ. *Human embryology.* New York: Churchill Livingstone; 1997.)

Clinical Correlation: Cystic Renal Disease

Autosomal recessive polycystic kidney disease occurs in approximately 1 : 20,000 live births. Most cases have a mutation in the *PKHD1* gene that results in microscopic cystic kidney disease and congenital hepatic fibrosis (Guay-Woodford et al., 2014). The severe renal disease often results in pulmonary hypoplasia causing neonatal death. In patients with nonlethal pulmonary status, early renal replacement by peritoneal dialysis and subsequent renal/liver transplantation has allowed survival (Chandar et al., 2015).

Clinical Correlation: Multicystic Dysplastic Kidneys

Multicystic dysplastic kidneys occur in approximately 1 : 2400 to 1 : 4800 newborns. In the majority of cases, this is a unilateral process with the nonaffected kidney exhibiting compensatory hypertrophy (Gaither et al., 2018). Multicystic dysplastic kidneys are characterized by nonfunctional renal tissue without recognizable glomeruli. The malformed tissue consists of noncommunicating cysts of various sizes with dysplastic tubular epithelium (Rojas et al., 2011). The etiology is not known but is thought to be related to abnormal signaling between the ureteral bud and the metanephric blastema. Treatment consist of documenting that the contralateral kidney remains healthy and compensates for the lack of function of the multicystic dysplastic kidney. The multicystic dysplastic kidney will typically involute over time and is not at risk for cancer or hypertension (Gaither et al., 2018). **Renal agenesis may be a nonrecognizable form of multicystic dysplastic kidney in which the involution occurs early in gestation before the abnormal renal development can be detected by prenatal sonogram.**

Key Points: Kidney Development

- The urinary system begins its development before genital system development becomes evident. With the formation of mesonephric ducts, embryonic kidneys develop sequentially in the order of pronephros (completely reabsorbed), mesonephros (partially reabsorbed), and metanephros (permanent kidney).
- The metanephros develops as a result of inductive interactions involving the ureteric bud (an outgrowth of mesonephric duct), condensing blastema of metanephric mesenchyme, and stromal cells.
- Renal tubulogenesis occurs via mesenchymal-epithelial conversion, whereas dichotomous branching of the ureteric bud leads to the formation of the collecting system.
- Selected gene mutations are associated with congenital anomalies of the kidney and urinary tract.
- As the kidneys migrate from the pelvis, they are vascularized by a succession of transient aortic sprouts that arise at progressively higher levels. The final pair of arteries forms in the upper lumbar region and becomes the definitive renal arteries.

Urologic Aspects of Pediatric Nephrology

Michael C. Braun MD, Chester J. Koh MD

Introduction

Although many parents and patients consider them to be the same specialty, pediatric urologists and pediatric nephrologists train through very different pathways and often provide different viewpoints on urinary tract abnormalities. This is especially with regard to surgical and medical management, respectively, of the kidneys and the urinary tract, where the two specialties are tightly partnered in the treatment of the anatomic and functional effects of urinary tract malformations and acquired diseases. This chapter is designed to highlight topics and viewpoints in pediatric nephrology of which pediatric urologists should be aware, where the collaborative expertise of pediatric nephrologists and pediatric urologists is usually needed for optimal acute and chronic patient care.

Renal Function, Fluid, and Electrolyte Homeostasis

Renal Development

Renal morphogenesis is a complex, temporally and spatially regulated process by which precursor cells develop into a structurally and functionally normal kidney. Abnormal or dysregulated renal development results in a wide range of renal abnormalities collectively known as **congenital anomalies of the kidney and urinary tract (CAKUT) and that compose the most common cause of end-stage renal disease (ESRD) in children**. In humans, kidney and urinary tract development begins at approximately 3 weeks' gestation with the formation of the initial urinary excretory precursor, the pronephros, which undergoes complete involution (Combes et al., 2015; Little et al., 2012; Short and Smyth, 2016). At roughly 4 weeks' gestation, the mesonephros forms, followed at 5 weeks by the metanephros. Unlike the pronephros, the mesonephros is both functional and integral to the mature urinary tract. In males, residual segments of the mesonephric duct form the vas deferens, prostate, the seminal vesicles, as well as part of the epididymis; segments of the mesonephric tubules form the testicular efferent ductules. In females, the mesonephric ducts persist as the epoophoron and paroophoron. The metanephros, arising from metanephric mesenchyme, forms the mature nephron segments. In contrast, the ureteric bud gives rise to the renal collecting duct, the renal pelvis, and the ureters. By 34 to 36 weeks' gestation, nephrogenesis is complete, and the structural and functional relationship of each nephron segment is fully developed. On average, 1 million (range 0.2 to 2.7 million) individual nephrons in each kidney arise from embryonic precursor cells.

Concurrent with the morphogenesis of the kidney, functional development of the fetal kidney also progresses with increasing gestational age. Prenatally, the placenta controls fluid and electrolyte homeostasis, and the primary function of the fetal kidney is the production of urine to maintain amniotic fluid volume. In the later stages of gestation, urine output, tubular function, and glomerular filtration increase with gestational age.

After birth, the neonatal kidney undergoes physiologic changes to adapt to the extrauterine environment; rapid changes occur over the first several weeks and continue until reaching adult levels at 1 to 2 years of life.

Glomerular Filtration Rate

Glomerular filtration rate (GFR) refers to the volume of filtrate formed by the movement of plasma across the glomerular filtration barrier per unit of time. GFR is influenced by a number of factors, one of which is renal blood flow. This relationship between renal blood flow and GFR is evident as changes in both occur during fetal and postnatal development (Schell et al., 2014). Prenatally, the percentage of cardiac output received by the placenta is significantly greater than the fetal kidney. Postnatally, renal blood flow increases from 3% to 4% of total cardiac output to between 12% to 16% in the first year of life (Quigley, 2012). The increase in neonatal renal blood flow is caused by a combination of increased cardiac output and a marked decrease in renal vascular resistance relative to the increase in cardiac output. Several factors mediate the decrease in renal vascular resistance. These include a redistribution of intrarenal blood flow distribution, with an increase in intrarenal blood flow from the juxtamedullary glomeruli located in deeper regions of the renal cortex to glomeruli in the outer renal cortex. Furthermore, the renin-angiotensin system (RAS) plays an important role regarding changes in renal blood flow. Increasing levels of angiotensin II increase mean arterial pressure and vasoconstriction of the renal efferent arteriole, which in turn increases GFR by increasing glomerular capillary pressure. **Plasma renin, angiotensin II, and angiotensin-converting enzyme (ACE) levels increase in late gestation and postnatally are higher in the first 2 weeks of life than in adulthood.** Additionally, prostaglandins and nitric oxide exert vasodilatory effects, lower renal vascular resistance, and counterbalance the vasoconstrictive effects of the RAS activation (Gleason, 1987).

Prenatal and neonatal GFR is significantly lower than adult GFR levels (Schwartz et al., 2009). Because of placental effects, plasma creatinine concentrations in the first 48 hours after delivery reflects maternal rather than neonatal renal function. Under normal circumstances, by 7 days of life, creatinine levels fully reflect neonatal renal function and are normally less than 0.5 mg/dL in term infants. Subsequently, GFR doubles in term infants over the first 2 weeks of life and increases steadily until reaching adult levels by 2 years of age.

Tubular Function

Glomerular filtration is only the first step in the homeostatic processes required of the kidney. Concurrent with the maturation of GFR, there are morphologic and physiologic changes, particularly with respect to the renal tubules, that lead to maturation of the ability to maintain fluid and electrolyte homeostasis.

Both term and preterm neonates possess a higher total body water than older children and adults that is as much as 70% to 90% of total body weight (Gattineni and Baum, 2015). Although neonates have the ability to dilute urine to as low as 50 mOsm/L, their urinary concentrating ability is limited, thus promoting negative free water balance. Normal free water loss is as much as 1% to 2% loss of total body weight per day over the first 5 days of life in term neonates and even higher in preterm neonates. There are a number of factors that reduce the ability of the neonatal kidney to generate a concentrated urine including decreased responsiveness to antidiuretic hormone (ADH) and immaturity of the renal tubules. The immaturity of the tubules is both structural and functional. Structurally, the renal tubules increase in length with age, particularly the thick ascending limb of the loop of Henle. At birth, the activity of the sodium-potassium ATPase (Na^+,K^+-ATPase) exchanger, which drives sodium transport, is low but increases in the immediate neonatal period, with a peak increase at around 2 to 3 weeks of life. Finally, there is an increase in the concentration of urea in the medullary interstitium, which is required for the generation and maintenance of the countercurrent multiplier that is essential for the formation of concentrated urine.

Developmental Changes in Glomerular Filtration Rate and Tubular Function

The maintenance of the balance of sodium is an important function of the neonatal kidney. The ability of a neonate to conserve sodium in the first week of life is limited with an ensuing initial negative sodium balance during the first week of life, which shifts to a positive sodium balance by 2 to 3 weeks of age. The natriuresis seen during the first week of life is mediated primarily by increased levels of atrial natriuretic peptide. The maturational responses to achieve sodium homeostasis include elongation of the tubular segments, which creates a larger surface area for reabsorption and upregulation of the number or activity of transporters in renal tubular cell membranes. Additionally, endocrine and paracrine mechanisms including the renin-angiotensin-aldosterone system (RAAS), catecholamines, cortisol, and thyroid hormone drive sodium homeostasis. Elevated levels of renin and aldosterone stimulate sodium reabsorption in the proximal tubule, the thick ascending limb of the loop of Henle, and cortical collecting ducts. Similarly, increased levels of catecholamines directly or indirectly through the RAAS pathway stimulate sodium reabsorption. Furthermore, increases in both cortisol and thyroid hormone stimulate tubular sodium transporters.

The newborn kidney has a limited capacity to excrete potassium and tends to have higher serum potassium values than older children. The limited renal capacity of the neonatal kidney to excrete potassium is thought to be caused by the reduced number and responsiveness of the Na^+,K^+-ATPase exchanger and the potassium transporters in the distal tubule and cortical collecting ducts. Normally, 65% to 75% of filtered potassium is passively reabsorbed by the proximal tubule (Palmer, 2015; Zhou et al., 2004). The remainder of potassium reabsorption occurs in the thick ascending limb of the loop of Henle via NKCC2, and much smaller amounts are reabsorbed in the distal tubule and cortical collecting ducts via the Na^+,K^+-ATPase exchanger. Urinary potassium excretion however is predominantly mediated via the apical renal outer medullary potassium (ROMK) channel of the cortical collecting ducts. Although the levels of circulating aldosterone are noted to be higher in neonates, the neonatal kidney has a decreased responsiveness to aldosterone activation. The postnatal increase in potassium secretory capacity is largely related to increased activity of the Na^+,K^+-ATPase exchanger and an increase in the number of ROMK channels in the cortical collecting ducts, which in turn increases tubular responsiveness to aldosterone.

In the neonate, the mechanisms of urinary acidification and bicarbonate reabsorption are immature, and neonatal serum bicarbonate levels are lower than that seen in adults. As renal acidification and bicarbonate reclamation improve over the first 3 to 4 weeks of life, there is a steady rise in net acid excretion and plasma bicarbonate reabsorption (Quigley et al., 2004). The primary site of bicarbonate reabsorption is the proximal tubule, where 80% of filtered bicarbonate is reabsorbed. The sodium-hydrogen exchanger 3 (NHE3) and H^+-ATPase, which both secrete H^+ into the proximal tubular lumen, drive HCO_3 reabsorption in the proximal tubule. Carbonic anhydrase IV (CA), which catalyzes the conversion of secreted H^+ and filtered bicarbonate (HCO_3) into carbon dioxide (CO_2) and water, are less active in the newborn, limiting the ability to absorb HCO_3 and secrete an acid load. With maturation, the activity of these mechanisms increases, resulting in a concurrent increase in serum HCO_3 concentration. The final step in urinary acidification occurs through the secretion of H^+ via the apical H^+-ATPase in the cortical collecting ducts. Maturational increases in the activity of this transporter is essential to acid-base homeostasis. A critical factor affecting this process is the postnatal increase in glucocorticoid production, which has been shown to promote an increase in the number of NH_3 antiporters, which are essential for ammonia generation.

At birth, neonatal serum levels of calcium are higher than those seen in adults (Schell-Feith et al., 2010). There is a fall in serum calcium levels in the first day of life. The maturation of renal tubular calcium regulation is not fully understood. Although there is a rise in serum parathyroid hormone (PTH) levels associated with the falling calcium levels, neonates are typically in negative calcium balance marked by relative hypercalciuria. It is likely that neonates have a blunted response to the effects of PTH either directly or indirectly, which limits proximal tubule calcium reabsorption through both paracellular and transcellular pathways and calcium reabsorption in the distal tubule by the TRPV6 channel. Neonates have a much higher renal reabsorption of phosphate compared with adults. Renal tubular reabsorption of phosphate can be as high as 99% immediately after birth and remain greater than 90% during the neonatal period (Kaskal et al., 1988). The reabsorption of phosphorus is mediated largely via the tubular transporters, such as the 2Na-Pi IIc antiporter, which are more active in the immature kidney. As circulating levels and tubular responses to PTH increase after birth, the level of phosphorus reabsorption falls as the kidney matures.

Key Points

- CAKUT is the most common cause of ESRD in children.
- Prenatal and neonatal GFR is significantly lower than adult GFR levels.
- The maintenance of the balance of sodium is an important function of the neonatal kidney.
- The newborn kidney has a limited capacity to excrete potassium and tends to have higher serum potassium values than in older children.

Hematuria (Microscopic and Gross)

Hematuria is one of the most common reasons for referral to pediatric nephrologists and urologists. Hematuria can present as either gross hematuria with red or “tea-colored” urine, or microscopic hematuria with yellow urine with a positive dipstick for blood. Microscopic hematuria is defined as clear yellow urine with a positive urine dipstick for blood with greater than five red blood cells per high-power field in a freshly spun urine sample. **Isolated microscopic hematuria is reported to occur in approximately 1% of school-age children** (Dodge et al., 1976; Vehaskari et al., 1979). Less than 25% of these children will have hematuria on repeated testing, and **most will have spontaneous resolution of hematuria within 1 year of presentation.** The incidence of gross hematuria is difficult to ascertain, however, it is estimated to account for slightly more than 0.1% of pediatric emergency room visits. Although isolated microscopic hematuria is most commonly a benign condition, the differential diagnosis is quite broad, and a definitive diagnosis is determined in less than 30% of patients. Gross hematuria typically prompts more urgent referral and evaluation, and in the majority of cases, an underlying diagnosis can be made.

A detailed history should be obtained to determine if the hematuria is painless, intermittent or persistent, and microscopic or gross. Associated symptoms should be sought including a history of trauma, abdominal pain, fever, dysuria, voiding dysfunction, rash, joint pain, weight gain, swelling, exercise, headaches, or visual changes. A detailed family history should also be obtained with a focus on hematuria, bleeding disorders, hearing loss, urolithiasis, sickle cell disease, and renal disease. Vital signs including blood pressure should be carefully measured. A thorough physical examination should be performed, with particular attention to blood pressure, rashes, joint abnormalities, edema, abdominal or flank pain, abdominal masses, and perineal abnormalities.

The critical step in the evaluation of hematuria is the examination of a freshly voided urine sample that includes microscopic assessment. Grossly bloody or red urine is indicative of nonglomerular bleeding, and brown or “tea-colored” urine is suggestive of a glomerular origin of the hematuria. In all patients with gross hematuria, urine microscopy is essential to confirm the presence of red blood cells (RBCs). **The absence of RBCs in grossly bloody urine with a positive urine dipstick for heme is strongly suggestive of hemoglobinuria or myoglobinuria.** The urine sediment should be examined closely for the presence of crystals, which are suggestive of urolithiasis, and the presence of white blood cells or bacteria are suggestive of urinary tract infection. A semiquantitative assessment of RBC number should be done, including RBC morphology, as uniformly normal RBC morphology is suggestive of lower urinary tract bleeding, and dysmorphic or “crenallated” RBCs are suggestive of glomerular disease. Urine sediment should be carefully examined for the presence of RBC casts, which define glomerular nephritis. In patients with suspected glomerular disease, a quantitative assessment of proteinuria should be performed. Based on the history, physical findings, and complete assessment of the urine, a logical and structured evaluation can be performed.

Patients with findings suggestive of glomerular disease, proteinuria, hypertension, edema, or evidence of systemic disease should have a baseline evaluation of their renal function, serum electrolytes, complete blood counts, serum albumin, complement C3 and C4 levels, and ASO or anti-DNase B titers. Referral to a pediatric nephrologist is often warranted. Renal cysts, most commonly in polycystic kidney disease, can also present with gross hematuria. Patients with fever, abdominal pain, dysuria, or frequency should have urine cultures done as urinary tract infections are the most common cause of gross hematuria in children. A history of trauma, abdominal or flank pain associated with gross hematuria often accompanied with frank clots should prompt urologic evaluation, and imaging by computed tomography (CT) is often warranted. In patients with a family history of urolithiasis, gross hematuria, abdominal or flank pain, and a history of passing gravel, imaging such as renal ultrasonography or CT should be done and also may include a comprehensive evaluation for renal stones. Other rare causes include urinary obstruction, tumors, coagulopathies, and vascular malformations.

The causes of hematuria in children are numerous (Box 21.1), and the assessment of children with microscopic hematuria is based on associated history and physical features combined with urinary findings. In patients with an unremarkable history including family history and who are asymptomatic and have only isolated microscopic hematuria without proteinuria, the evaluation can be limited to testing the parents for hematuria and measurement of urinary calcium excretion. The value of urinary tract imaging in children with microscopic hematuria is controversial. The yield of routine ultrasonography is low, and reported findings are frequently of little clinical significance. When microscopic hematuria persists for several months, decisions on the need for urinary tract imaging should be based on associated clinical findings. Voiding cystourethrograms and cystoscopy are rarely helpful and are not indicated for the routine evaluation of children with isolated microscopic hematuria. In patients with a positive family history, personal history, abnormal physical findings, or urinary findings in addition to hematuria, a more comprehensive evaluation is recommended. Typically this would include a complete blood count, serum electrolytes, creatinine, albumin, C3, C4, ASO titer, antinuclear antibody (ANA) testing, and a quantitative measurement of urinary protein excretion. Additional testing such as hearing screening, hemoglobin electrophoresis, imaging, and genetic testing should be individualized.

Box 21.1

Causes of Hematuria in Children

Macroscopic

- Transient
- Hypercalciuria/nephrolithiasis
- Glomerulonephritis (all types)
- Cystitis
- Exercise
- Congenital anomalies of the urinary tract
- Benign urethrorrhagia
- Wilms tumor or bladder tumor
- Bleeding dyscrasia
- Renal vein thrombosis
- Papillary necrosis
- Nutcracker syndrome

Microscopic

- Transient
- Hypercalciuria/nephrolithiasis
- Glomerulonephritis (all types)
- Cystitis/pyelonephritis
- Exercise
- Congenital anomalies of the urinary tract

Thin basement membrane disease
Drugs
Interstitial nephritis
Sickle cell disease/trait

Key Points

- Isolated microscopic hematuria is reported to occur in approximately 1% of school-age children.
- Most children with microscopic hematuria will have spontaneous resolution within 1 year of presentation.
- Gross hematuria and a urinalysis with no RBCs and a positive heme dipstick is strongly suggestive of hemoglobinuria or myoglobinuria.

Proteinuria

Proteinuria is another common finding that prompts referral to a pediatric subspecialist. **It is important to recognize that urine contains protein under physiologic conditions and that children excrete urine free of protein frequently when evaluated by the semiquantitative dipstick method.** Urinary protein excretion varies by body mass and renal maturity. A normal urine protein-to-creatinine ratio in a newborn is less than 0.7 mg/mg, and less than 0.2 mg/mg in older children. If a timed collection is obtained, physiologic urinary protein excretion is typically less than 4 $mg/m^2/h$. Healthy adolescents and adults excrete less than 150 mg of protein in a 24-hour period. Urinary protein consists of both filtered plasma proteins and secreted tubular proteins. Although most filtered proteins are of low molecular weight, albumin accounts for nearly 30% of the total protein found in “normal” urine.

Proteinuria is categorized as either transient, orthostatic, or fixed (Box 21.2) (Hogg et al., 2000; Vehaskari and Rapola, 1982). **Transient proteinuria is characterized by disappearance of proteinuria after a positive test and accounts for more than 75% of patients with isolated proteinuria. Typically, transient proteinuria occurs in association with fever or exercise.** In an otherwise healthy child, transient proteinuria is a benign condition. Orthostatic proteinuria commonly occurs in adolescents and is defined as proteinuria only when the patient is in an upright position. Patients are otherwise healthy and do not have other evidence of renal disease. A diagnosis of orthostatic proteinuria is made by the measurement of urinary protein in the first-void urine and in a second sample after the patient has been upright for several hours (Abitbol et al., 1990). In orthostatic proteinuria, the initial first-void urine sample has normal protein values (protein-to-creatinine ratio <0.2 mg/mg), and the upright urine has increased levels of urine protein. Orthostatic proteinuria is usually transient and benign in nature; however patients should be closely evaluated to confirm that they are otherwise asymptomatic and have normal renal function and blood pressure. It is recommended that patients with orthostatic proteinuria be followed annually to ensure that there is no progression in their clinical findings. Fixed proteinuria is persistent and not dependent on postural changes. Protein excretion should be quantified either by a timed collection if possible or by first-void urine protein-to-creatinine ratio. Fixed proteinuria requires a more thorough evaluation.

Box 21.2

Causes of Proteinuria

- Transient
  - Exercise
  - Fever
  - Stress/illness
- Orthostatic
- Fixed
  - Drugs (chemotherapy, aminoglycosides, heavy metal intoxication)
  - Tubular disease (acute tubular necrosis, interstitial nephritis, cystic kidney diseases, Fanconi syndrome, graft-versus-host disease)
  - Reflux nephropathy
  - Glomerulonephritis: acute and chronic, all forms, including minimal change nephrotic syndrome
  - Other chronic renal disease (obstructive uropathy, congenital renal dysplasia, permanent residual dysfunction from acute disease [e.g., cortical necrosis, hemolytic uremic syndrome, glomerulonephritis])
  - Diabetes mellitus
  - Protein overload syndromes (hemolysis, rhabdomyolysis, hypergammaglobulinemia)

The differential diagnosis of proteinuria is quite broad, and the evaluation of patients with persistent proteinuria should be focused on identifying the underlying etiology of the proteinuria. It is essential to obtain a complete and thorough history and physical examination including a comprehensive family history with attention to family members with autoimmune disease, renal disease, diabetes, and ESRD. Associated symptoms should be sought including a history of fever, gross hematuria, excessive urinary foaming, growth failure, rash, joint pain, weight gain, swelling, headaches, or visual changes. Vital signs including blood pressure should be carefully measured. A thorough physical examination should be performed with particular attention to blood pressure, rashes, joint abnormalities, and edema. Laboratory investigation should be tailored to findings on the history and physical examination, but often include measurement of serum creatinine, albumin, electrolytes, complete blood count, cholesterol, and triglycerides. **If the patient has evidence of systemic disease or glomerular nephritis, testing should include C3, C4, and ANA screening.** Further diagnostic testing will be dependent on the results of these screening tests. If the screening studies are normal and the patient has persistent proteinuria, renal biopsy may be warranted to determine the underlying diagnosis.

Key Points

- It is important to recognize that urine contains protein under physiologic conditions and especially with fever and exercise.
- Transient proteinuria accounts for more than 75% of patients with isolated proteinuria.
- If a patient with proteinuria has evidence of systemic disease or glomerular nephritis, testing should include C3, C4, and ANA screening.

Glomerular Disease

Glomerular diseases in children have several etiologies, and they commonly present in specific age ranges (Box 21.3).

Box 21.3

Common Age Ranges for Presentation of Glomerular Diseases

Younger Than 1 Year of Age

- Congenital infections
- Diffuse mesangial sclerosis
- Genetic diseases:
  - Congenital nephrotic syndrome (CNS) and infantile nephrotic syndrome
  - Denys-Drash and Frasier syndromes

1 to 10 Years of Age

- Acute poststreptococcal glomerulonephritis (GN)
- Minimal change nephrotic syndrome (MCNS)
- Focal segmental glomerulosclerosis (FSGS)
- Henoch-Schönlein purpura (HSP)
- Hemolytic uremic syndrome (HUS)

7 Years of Age and Older

- Systemic lupus erythematosus (SLE)
- Systemic vasculitis
- Idiopathic crescentic GN
- Membranoproliferative GN (MPGN)
- Immunoglobulin A nephropathy
- Idiopathic and secondary FSGS

Membranous nephropathy (MN)
Alport syndrome
Nail-patella syndrome
Pulmonary-renal syndromes (Goodpasture syndrome [antiglomerular basement memebrane disease])

Nephrotic Syndrome

Nephrotic syndrome is a constellation of clinical findings common to a number of glomerular diseases. These features include proteinuria greater than 40 $mg/m^2/h$ or a urinary protein-to-creatinine ratio greater than 2.0 mg/mg, hypoalbuminemia, and hyperlipidemia. The reason for the increased hepatic production of lipoproteins during the nephrotic state is not entirely understood, but it appears to be associated with low plasma oncotic pressure and alterations in lipoprotein metabolism. **Although nephrotic syndrome may present as a feature of glomerular nephritis, it presents more commonly in children in isolation**.

Nephrotic syndrome of childhood has been divided into three broad groups: congenital/infantile, primary (inherited or idiopathic), and secondary. Approximately 10% of children have an identifiable secondary cause of nephrotic syndrome. The histologic lesions that are associated with secondary causes of nephrotic syndrome are frequently indistinguishable from the idiopathic lesions, but the treatment is targeted to the primary underlying cause in these cases. Over the past two decades, mutations in nearly 30 genes have been identified in either inherited or sporadic primary nephrotic syndrome.

Primary nephrotic syndrome is the occurrence of the constellation of clinical findings that define NS in the absence of an identifiable causative agent or disease. Primary NS is classified into four categories based on histologic findings: minimal change nephrotic syndrome (MCNS), mesangial proliferation (MES), focal segmental glomerulosclerosis (FSGS), and membranous nephropathy (MN). Nephrotic syndrome is classified by responsiveness to steroid therapy and histopathologic features if a biopsy is performed.

Steroid-sensitive nephrotic syndrome (SSNS) typically presents with dependent edema with variable swelling of the eyelids, scrotum, and labia. Hypertension is not typical. Microscopic hematuria is seen in approximately 20% of patients. Macroscopic hematuria is unusual.

Corticosteroids will induce a remission in the vast majority of children

with nephrotic syndrome. Therefore, for those with a typical clinical presentation, a kidney biopsy is not indicated before initiating steroid therapy. Atypical features that may require a kidney biopsy before treatment include age younger than 1 year at presentation, macroscopic hematuria, hypertension, hypocomplementemia, and extrarenal symptoms such as a rash or arthritis.

Edema is mild in most patients and can be managed with dietary restriction (Teoh et al., 2015). The current standard of care is to treat these children with corticosteroids. Most children receive initial treatment with prednisone (60 mg/m^2/day or 2 mg/kg/day). The current definition of steroid responsiveness is a resolution of proteinuria within 8 weeks of starting steroid therapy. Once the urine become negative for protein, the prednisone is switched to alternate days and tapered over 6 weeks or longer. Almost 50% of children with SSNS will experience multiple relapses (Teeninga et al., 2012).

Frequently-relapsing nephrotic syndrome (FRNS) is defined as two or more relapses within 6 months of initial response to steroid therapy or four or more relapses within any 12-month period. In this setting, the potential adverse effects of the cumulative steroid doses required to achieve sustained remission begin to exceed the benefits of maintaining nephrotic syndrome remission. Steroid-sparing strategies have also been developed to treat FRNS including alkylating agents such as oral cyclophosphamide, mycophenolate mofetil (MMF), B-cell depletion with rituximab, and calcineurin inhibitors (CNIs).

Steroid-dependent nephrotic syndrome (SDNS) is defined when a child with NS develops two consecutive relapses during steroid therapy or when the ability to achieve and/or remain in remission from nephrotic syndrome requires continuous administration of corticosteroids. Steroid-sparing strategies in this population include low-dose alternative-day corticosteroids, MMF, B-cell depletion with rituximab, and CNIs. Children with SDNS tend not to respond as well to alkylating agents as the FRNS subgroup.

Steroid-resistant nephrotic syndrome (SRNS) is seen in 15% to 20% of children with idiopathic NS and in a small subset of patients who were initially steroid responsive. It is defined as a failure to achieve remission after 6 to 8 weeks of full-dose daily prednisone. A biopsy is often recommended for steroid-resistant patients before initiating alternative therapies as there is a much higher prevalence of FSGS in this subset of patients (Lovric et al., 2015). A wide range of therapies has been utilized in patients with SRNS, with varying degrees of efficacy including intravenous pulse steroids, combined treatment with high-dose corticosteroids and alkylating agents, and cyclosporine or tacrolimus

(Büscher et al., 2016). Patients who achieve remission with CNIs are reported to have a high frequency of relapse when these agents are discontinued. Patients who are refractory to steroids and CNIs rarely respond to other therapies.

Congenital nephrotic syndrome (CNS) is defined as nephrotic syndrome presenting within 3 months after birth. CNS can be caused by either genetic defects or perinatal infections. Proteinuria often begins in utero and can be detectable in the first urine sample after birth. In cases of CNS, immunosuppressive therapy is not recommended as patients have been shown to be nonresponsive to these agents. Conservative management of edema consists of sodium and fluid restriction and intermittent intravenous albumin and loop diuretics. The management of these patients also includes a hypercaloric diet, thyroid hormone replacement, monitoring for thrombotic episodes, and aggressive management of infectious complications.

Minimal change nephrotic syndrome (MCNS) is the most common cause of nephrotic syndrome in childhood, accounting for 90% of patients presenting before 10 years of age and 70% to 80% of all pediatric patients with nephrotic syndrome. MCNS is characterized by response to corticosteroids and often a chronic relapsing course. Most patients have an excellent long-term prognosis. The peak incidence is in preschool children, with a median age of 2.5 years. MCNS is usually idiopathic in childhood, although there is a wide range of secondary causes of MCNS and an increasing number of genetic mutations linked to MCNS. The cornerstone of therapy for MCNS is corticosteroids, which will induce remission in nearly 90% of children. Up to 85% of patients achieve long-lasting remission. However, a subset of patients will continue to experience relapses into adulthood.

Focal segmental glomerulosclerosis (FSGS) is seen in the majority of children with SRNS. FSGS may be primary or secondary. As opposed to MCNS, less than 25% of patients with FSGS respond to steroid therapy. In children, primary FSGS typically presents between 2 and 7 years of age, with a higher incidence among African-Americans, Hispanics, and Asians. Genetic etiologies of steroid-resistant FSGS have been identified with increasing frequency. The vast majority of children with idiopathic FSGS present with nephrotic syndrome that is indistinguishable from SSNS. Definitive diagnosis requires kidney biopsy. Current guidelines recommend initial treatment of primary FSGS with high-dose prednisone for durations of 4 to 16 weeks or until complete remission. CNIs are often recommended for patients who are resistant or intolerant to corticosteroids. **FSGS can recur after kidney transplantation.** Treatment with plasmapheresis, B-cell depletion, and CNIs has been reported to be effective in some patients. However, many will lose their graft and return to dialysis.

Membranous nephropathy (MN) is a rare cause of nephrotic syndrome in childhood. The majority of childhood cases of MN are secondary to an underlying disorder; autoantibodies to phospholipase A_2 receptor (aPLA_2R) are frequently seen in children and adolescents with primary MN (Cossey et al., 2013). Hepatitis serology, serum complement levels, and ANA testing should be obtained. A kidney biopsy is required to establish a diagnosis. On biopsy, MN is characterized by the presence of subepithelial immune deposits. There are no universally accepted treatment guidelines for children with MN. The use of ACE inhibitor or angiotensin receptor blocker (ARB) therapy and a low-sodium diet are recommended. Corticosteroids alone can decrease proteinuria, but rarely leads to long-term remission when used in isolation. For this reason, corticosteroids are often used combined with an alkylating agent. CNIs are also commonly used. Recent data suggest that MMF and rituximab may be efficacious in MN secondary to PLA_2R-AB. MN is typically a slowly progressive disease, with 5% of children developing ESRD 5 years after diagnosis.

Persistence of nephrotic syndrome is associated with significant morbidity and even mortality. Because nephrotic syndrome frequently follows a chronic relapsing course, children are at risk for several recognized long-term complications. Spontaneous bacterial peritonitis occurs in 2% to 6% of these children and is typically caused by *Streptococcus pneumoniae* or gram-negative organisms. **Thromboembolism is one of the most serious complications of nephrotic syndrome.** Virtually all nephrotic patients are in a hypercoagulable state, and as many as 20% experience thrombotic events. Mortality, although rare, is most frequently caused by infectious complications and less commonly by thromboembolic events.

Glomerulonephritis

As opposed to isolated nephrotic syndrome, **glomerulonephritis classically presents with hematuria (gross or microscopic), proteinuria, hypertension, and acute kidney injury.** Inflammation leads to decreased renal function and retention of salt and water with ensuing hypertension and edema. Urinary features typically include “tea-colored” or “cola-colored” urine, with a urine sediment characterized by dysmorphic erythrocytes and red blood cell casts

(Kidney Disease Improving Global Outcomes [KDIGO], 2012). Although glomerular diseases can occur in almost any age group, most have a characteristic age range for disease onset. A number of systemic diseases may have their initial presentation with glomerulonephritis, so a careful examination for signs and symptoms of multisystem disease should be sought. It is essential to recognize that many patients with chronic glomerulonephritis may be asymptomatic in the early stages of disease progression. Therefore it is essential to determine if there is evidence of chronic kidney disease (CKD) at the time of initial evaluation. Features of CKD include anemia, growth failure, and the hallmarks of chronic kidney disease/mineral bone disease (CKD/MBD): hyperparathyroidism, hypocalcemia, and hyperphosphatemia. Initial laboratory evaluation of children with glomerulonephritis is focused on defining the severity of acute kidney injury, any metabolic derangements associated with decreased renal function, and whether the child has evidence of hypocomplementemia which, if present, significantly narrows the differential diagnosis. Hypocomplementemia, defined by a low C3 level when combined with normal C4 levels, is strongly supportive of a diagnosis of acute postinfectious glomerulonephritis or C3 glomerulopathy, and a low C3 level and a low C4 level focuses the diagnosis on either lupus nephritis or membranoproliferative glomerulonephritis. Normocomplementemia is a feature of the other common forms of glomerulonephritis that are seen in the pediatric population.

Acute poststreptococcal glomerulonephritis is the most common form of post-infectious glomerulonephritis (PIGN) in childhood. However, many other bacterial, viral, and parasitic pathogens are also associated with PIGN. Typically the child has a history of pharyngitis or pyoderma that precedes the presentation of glomerulonephritis by several weeks. Acute poststreptococcal glomerulonephritis is primarily a disease of school-age children. It is rare before 3 years of age and may occur as a sporadic or epidemic disease.

Clinical symptoms begin abruptly, with most patients presenting with edema and gross hematuria. Proteinuria is typically mild; however some patients can present with features of nephrotic syndrome. Mild to moderate hypertension is common, although some patients with severe disease present with hypertensive urgency or emergency. Acute kidney injury is typically mild, although in severe cases, rapidly progressive glomerulonephritis (RPGN) can occur, necessitating renal replacement therapy (RRT). Laboratory testing supportive of a diagnosis of PIGN includes a serum C3 level usually below 50% of normal levels, and an elevated ASO or DNase B titer. In the vast majority of cases, with conservative management, spontaneous improvement typically begins within 1 week, with resolution of the edema occurring in 5 to 10 days, and resolution of the hypertension occurring in 2 to 3 weeks. In the majority of patients, the clinical presentation and laboratory testing that includes complement levels is usually sufficient to make the diagnosis of PIGN, and there is no indication to perform a kidney biopsy to confirm the diagnosis. C3 levels typically return to normal within 8 to 12 weeks after presentation. However, if a child has persistently low C3 levels or has an atypical clinical course, a kidney biopsy may be indicated. Residual proteinuria may be present of up to 6 months after the acute injury, and microscopic hematuria may persist for more than 1 year.

Two other forms of hypocomplementemic nephritis, although rare, can present in childhood: **Membranoproliferative glomerulonephritis (MPGN)** and **C3 glomerulopathy (C3G),** which is further subdivided into dense deposit disease and C3-dominant glomerulonephritis (C3GN). These diseases typically present in late childhood and are rare before 5 years of age. The presentation of MPGN/C3G is varied and includes asymptomatic hematuria or proteinuria, nephrotic syndrome, and features that initially mimic PIGN, including low serum C3 levels in the remainder (Pickering et al., 2013). The presence of nephrotic syndrome and a depressed serum C4 level are early clues that differentiate MPGN from PIGN. Persistent hypocomplementemia in a patient with suspected PIGN is highly unusual and is suggestive of either G3G or MPGN. Although many MPGN patients have evidence of activation of the classical complement cascade with low serum C3 levels and low C4 levels, and patients with C3G patients commonly have signs of alternative pathway activation with persistently low C3 and normal C4 levels, these distinctions are not absolute and a kidney biopsy is required to establish the diagnosis of MPGN/C3G.

The final form of hypocomplementemic nephritis that presents in childhood is **systemic lupus erythematosus (SLE) and should be considered a likely diagnosis in any child with evidence of systemic disease, glomerulonephritis, and low C3 and C4 levels** (Hiraki et al., 2012). The clinical presentation of SLE ranges from asymptomatic microscopic hematuria or proteinuria to rapidly progressive glomerulonephritis. Usually other systemic manifestations of SLE are apparent. The presence of 4 out of 11 American College of Rheumatology classification criteria for SLE confers a 96% sensitivity and specificity for the diagnosis of SLE. Almost all patients have hypocomplementemia, positive antinuclear antibodies, and anti–double-stranded DNA titers. No combination of serologic markers effectively predicts the histologic type or severity of kidney involvement. The treatment of patients with mild renal disease (classes I and II) should be determined by the extrarenal manifestations and typically have a favorable renal prognosis. However, children with more extensive renal involvement (class III and IV) can have more progressive renal dysfunction if left untreated. Consensus treatment recommendations developed for children with SLE include the use of corticosteroids combined with immunosuppressive drugs in this patient population (Mina et al., 2012). However, only 80% of patients with class IV achieve sustained remission, and up to 50% of patients will experience at least one relapse.

Normocomplementemic Glomerulonephritis

Immunoglobulin A (IgA) nephropathy is the most common primary cause of glomerulonephritis throughout the world including in the pediatric population. Patients with this condition commonly present in the second and third decades of life, and it is rare in the first decade of life. The true incidence of IgA nephropathy is uncertain, as there are no reliable serologic markers, and a renal biopsy is the only way to definitively make the diagnosis. IgA nephropathy is defined by the presence of dominant IgA deposits in the glomerulus. These deposits are polymeric IgA1 with aberrant glycosylation patterns in the hinge region of the antibody (Kiryluk et al., 2011).

Most commonly, these patients present with recurrent episodes of painless macroscopic hematuria. The onset of gross hematuria is often concurrent with or immediately proceeded by an upper respiratory tract infection. The latency period between the onset of infectious symptoms and gross hematuria is considerably shorter in IgA nephropathy than that seen in patients with PIGN. The gross hematuria episodes typically resolve within a few days, but microscopic hematuria and variable degrees of proteinuria may persist. Occasionally there are complaints of flank or loin pain associated with the gross hematuria. Many patients will also present with incidental findings of microscopic hematuria and mild proteinuria. Less commonly, patients will present with isolated nephrotic syndrome. Most of the acute episodes resolve without specific therapy, and the long-term prognosis remains relatively good. There are currently no diagnostic markers for IgA nephropathy. A renal biopsy for suspected IgA nephropathy may be considered in patients who have impaired kidney function, hypertension, or significant proteinuria, as these individuals are at increased risk for developing ESRD. IgA nephropathy is a disease with a highly variable outcome. For patients with self-limited episodes of recurrent gross hematuria who do not develop significant proteinuria, the long-term outcome is quite good. Risk factors for progressive disease include persistent and significant degrees of proteinuria, hypertension, and an elevated serum creatinine. In the high-risk patient population, kidney function slowly deteriorates. Current data suggest that up to 20% to 30% of this population will develop ESRD and another 20% have progressive CKD.

Henoch-Schönlein purpura (HSP) is a self-limited systemic vasculitis syndrome of childhood characterized by symptoms that may occur asynchronously over a period of several days to weeks. These features include a purpuric rash, arthralgia, abdominal pain, and glomerulonephritis. Nephritis rarely, if ever, precedes the onset of purpura. Histologically, the glomerulonephritis in HSP is indistinguishable from idiopathic IgA nephropathy. Whereas IgA nephropathy is exclusively a renal disorder, HSP is characterized by its extrarenal manifestations. The pathophysiology is similar in its involvement of glomerular deposition of polymeric IgA1 immune complexes (Kiryluk et al., 2011). Most patients with HSP nephritis present with asymptomatic hematuria and mild proteinuria, although up to one-fourth of these patients develop gross hematuria. A small subset of patients will present with an acute nephritis and/or nephrotic syndrome, and presentation with RPGN is rare. HSP remains a clinical diagnosis as there are no specific diagnostic markers for this condition. Kidney biopsy is not necessary for diagnosis but can be helpful in making treatment decisions when patients develop nephrotic syndrome or RPGN. HSP usually spontaneously resolves within 1 to 2 weeks, but recurrent episodes occur fairly commonly for the first 4 months. Ultimately the vast majority of patients achieve full clinical remission (Dudley et al., 2013). Persistent urinary abnormalities, low-grade proteinuria, and microscopic hematuria is commonly seen for up to 3 months after presentation and for up to 2 years in 10% to 20% of children. A rapidly progressive clinical course with ensuing ESRD can be seen in a small percentage of patients. Patients with persistent heavy proteinuria may see progression over a period of several years. In a long-term follow-up study of patients with HSP, 44% of patients with nephrotic syndrome or acute nephritis at presentation developed hypertension or progressive CKD, compared with normal renal function in 82% of patients who presented with isolated hematuria.

Alport syndrome is a genetic disorder of the collagen type IV α3, α4, or α5 chains that form the mature glomerular basement membrane. The primary presenting clinical finding in all forms of Alport syndrome is persistent microscopic hematuria. Intermittent gross hematuria is also commonly seen. **Sensorineural deafness is a common feature that distinguishes Alport syndrome from other forms of glomerular disease.** Hearing deficits typically occur in late childhood, are bilateral, and initially involves high-frequency hearing loss that gradually worsens over time. A family history of kidney failure or deafness in a child with hematuria is highly suggestive of Alport syndrome. Ocular anomalies may develop later in childhood, including macular disease and anterior lenticonus. Other rare associations include leiomyomata of the esophagus, trachea, and the external genitalia in females. Alport syndrome has X-linked, autosomal dominant, and recessive forms of inheritance (Savige et al., 2016). The majority of patients have X-linked mutations in *COL4A5*, the gene encoding the α5 chain of collagen type IV. Autosomal disease is caused by mutations in *COL4A3* or *COL4A4*. Heterozygous mutations in *COL4A3* or *COL4A4* are inherited in a dominant fashion, and patients with mutations in both alleles present in a recessive manner. Kidney function is usually well preserved during the first decade of life in males with X-linked Alport syndrome. Frank proteinuria frequently appears during late childhood or early adolescence and is followed by development of hypertension and renal insufficiency (Savige et al., 2013). About 50% of males with X-linked disease reach ESRD by 25 years of age. Patients with autosomal recessive disease follow a course similar to males with X-linked Alport syndrome. There are no disease-specific treatments for Alport syndrome, and therapy is focused on reducing the rate of progression with RAAS inhibition to reduce proteinuric renal injury and to control hypertension (Kashtan et al., 2013).

Antineutrophilic cytoplasmic antibody (ANCA)-associated glomerulonephritis is a rare disease in childhood. Two target ANCA antigens have been identified: proteinase-3, or cANCA, and myeloperoxidase, or pANCA. ANCA-associated glomerulonephritis in childhood is divided into two small-vessel vasculitic syndromes: microscopic polyangiitis (MPA) and granulomatosis with polyangiitis (GPA) (Cabral et al., 2016). Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome) is extremely rare in childhood. Although ANCA-associated glomerulonephritis occurs primarily in adults, it can present in adolescence and occasionally during childhood. Nephritis is seen in 70% to 80% of children with either GPA or MPA. The features of GPA and MPA overlap where both typically present with a flulike prodrome and systemic symptoms such as fever, anorexia, malaise, weight loss, myalgias, arthritis and/or arthralgias, and skin lesions (purpura or urticaria). Lung disease occurs in both syndromes and can include life-threatening pulmonary hemorrhage. Granulomatous involvement of the upper airway, sinuses, nasal passages, and ears is present in many patients with GPA but not in MPA. A small subset of patients present with renal-limited vasculitis. Histologically, the principal finding is pauci-immune focal necrotizing glomerulonephritis, which is similar in both GPA and MPA and is often severe. All patients with nephritis have hematuria, most have proteinuria, and more than 70% have decreased renal function at diagnosis. Some patients present with RPGN. ANCA are detected in 85% to 95% of patients with active GPA (PR3-cANCA) and 70% with MPA (MPO-pANCA). ANCA-associated systemic vasculitis is an aggressive disease. Without treatment, mortality rates are 90% within 2 years. Patient and kidney survival have improved dramatically with intensive immunosuppressive therapy, however relapses are common. CKD persists in as many as one-half of patients, with nearly one-fourth of patients eventually developing ESRD.

Antiglomerular basement membrane (Anti-GBM) disease is an aggressive form of glomerulonephritis that is rarely seen in childhood. It is mediated by antibodies to the glomerular basement membrane. **Known as Goodpasture syndrome when associated with pulmonary hemorrhage,** it is rare in the first decade of life but has been reported in children as young as 2 years of age. Anti-GBM nephritis may occur as a rare complication after extracorporeal shock wave lithotripsy (ESWL), membranous nephropathy, or minimal-change disease. Anti-GBM nephritis may also occur in a small subset of patients with Alport syndrome after kidney transplantation. The Goodpasture target antigen is the carboxy-terminal region (NC1 domain) of the α3 chain of collagen type IV, the structural component of glomerular and pulmonary basement membranes. Patients present with acute nephritis or less commonly with symptoms of CKD. Pulmonary hemorrhage presenting as hemoptysis often precedes or accompanies the onset of nephritis; these episodes of hemoptysis may be life-threatening. More than 90% of patients have anti-GBM antibodies at the time of clinical presentation. Progression to irreversible kidney injury can occur within weeks. **The mainstay of therapy is plasmapheresis to remove the circulating antibody combined with immunosuppressive therapy to reduce new antibody production.** The kidney disease is unlikely to be reversible unless treatment is started early. Patients who recover from the acute disease generally do well, and disease relapses are extremely rare.

RPGN is a rare disorder in childhood that is traditionally divided into three groups; anti-GBM nephritis, immune complex nephritis, and pauci-immune disease associated with ANCA. Less commonly, other forms of proliferative glomerulonephritis may present as severe crescentic disease. This clinical syndrome is characterized by sudden onset and rapid decline in kidney function. It typically presents with gross hematuria, edema, anemia, and hypertension. Isolated nephrotic syndrome is uncommon. Pulmonary hemorrhage suggests a diagnosis of anti-GBM nephritis or ANCA vasculitis and may be fatal if treatment is delayed. Serologic studies including a C3, C4, ANA, ANCA, and anti-GBM antibodies should be obtained; however, a biopsy confirmation is essential and establishes the diagnosis in most patients. The renal biopsy commonly shows extensive crescent formation. Therapy is directed to the specific disease entity. Spontaneous resolution of RPGN is extremely unlikely. The prognosis is poor unless aggressive therapy is started early in the course of the disease.

Hemolytic uremic syndrome (HUS) is a common cause of severe acute kidney injury in a previously healthy young child. **The majority of children with HUS have an antecedent diarrheal illness caused by Shiga toxin–producing *Escherichia coli* (STEC).** Approximately 10% of HUS cases are not associated with STEC infections and are referred to as atypical HUS (aHUS). HUS, aHUS, and thrombotic thrombocytopenic purpura (TTP) are classified as forms of thrombotic microangiopathy (TMA), however the triggers, primary target organs, response to treatment, and clinical outcomes are distinct. HUS occurs in both sporadic and epidemic patterns. More than 70% of children in the United States with STEC-positive HUS have been infected with *E. coli* 0157:H7. The primary reservoir for *E. coli* 0157:H7 is farm animals, although contamination of fruits, juices, and vegetables is also common. HUS is initiated by damage to the endothelium with microthrombi formation, leading to the diagnostic triad of microangiopathic hemolytic anemia, thrombocytopenia, and acute kidney injury. In patients with aHUS, defects in regulation of the alternative complement pathway are commonly found (Loirat et al., 2015). These include mutations in complement factor H, factor I, membrane cofactor protein, C3, complement factor B, and autoantibodies against complement factor H and factor I. In young children, aHUS can occur as a complication of *S. pneumoniae* infection. Unlike other patients with HUS, these patients have a positive Coombs anemia. Of note, the use of fresh-frozen plasma is contraindicated in patients with pneumococcal-associated HUS.

After ingestion of *E. coli*–contaminated food, most affected children develop abdominal pain and bloody diarrhea. The colitis is usually self-limited, but complications may occur, including rectal prolapse, toxic megacolon, bowel wall necrosis, and bowel perforation. The onset of HUS is usually abrupt, occurring within 1 week after the onset of the diarrhea. The presenting symptoms are often caused by acute kidney injury. The severity of the acute kidney injury is highly variable, but one-half will develop oligoanuria and require dialysis. Hypertension is variable but may be severe. The mean duration of the acute kidney injury is 2 weeks. In aHUS, the antecedent illness is more nonspecific, often associated with fever, upper respiratory symptoms, and vomiting. Sometimes a prodromal illness is not apparent. Neurologic involvement is common and can mimic TTP. Most patients are very irritable and somnolent, and seizures and coma can occur in 10% of children. Virtually any organ can become damaged by the microvascular thrombi. Anemia is characterized by the presence of schistocytes, negative Coombs test, elevated reticulocytosis and lactose dehydrogenase levels, and a low serum haptoglobin. The prothrombin and partial thromboplastin time are usually normal. Serum C3 level and CH50 may be depressed in both STEC-positive HUS and aHUS but is more common in those with aHUS; an abnormal serum C3 level does not rule out the possibility of a genetic complement deficiency. In patients with clinical features suggestive of STEC-positive HUS, confirmation of a Shiga toxin–producing *E. coli* either by culture or the presence of the Shiga toxin is recommended. When aHUS is a consideration, it is important to measure ADAMT13 activity and inhibitor testing to rule out TTP and to evaluate the complement system by protein and genetic testing. For STEC-positive HUS, supportive medical care is by far the most important aspect of treatment. Meticulous attention must be paid to fluid and electrolyte management. **Severe acute kidney injury requiring dialysis still develops in nearly one-half of patients.** Packed red blood cell transfusions should be reserved for patients with clinical indications of severe anemia. Platelet transfusions should be avoided unless the patient is actively bleeding or the platelets are needed in preparation for an invasive procedure. During the prodromal phase of colitis, antimotility drugs are contraindicated, and antibiotics should be avoided as they have been reported to increase the probability of developing HUS. For patients with aHUS, Eculizumab, a monoclonal antibody to the complement component C5, is the therapy of choice. It has been shown to be highly effective in patients with complement dysregulation. Acute mortality in STEC-positive HUS is related to severe complications such as neurologic disease, cardiac failure, and multiorgan involvement. Kidney function typically improves spontaneously, and almost all patients are able to discontinue dialysis. However, long-term follow-up studies suggest that 5% to 25% of patients will develop CKD. aHUS generally follows a more severe clinical course and is more likely to relapse in the absence of chronic complement inhibition. Recurrent disease in either native kidneys or after kidney transplant is extremely rare in STEC-positive HUS but is quite common in aHUS. Eculizumab treatment is also recommended for aHUS patients undergoing kidney transplantation.

Key Points

- Corticosteroids will induce a remission in the vast majority of children with nephrotic syndrome.
- Focal segmental glomerulosclerosis is seen in the majority of children with steroid-resistant nephrotic syndrome.
- Minimal change nephrotic syndrome is the most common cause of nephrotic syndrome in childhood.
- IgA nephropathy is the most common primary cause of glomerulonephritis throughout the world.
- Hemolytic uremic syndrome is a common cause of severe acute kidney injury in a previously healthy young child.

Tubulopathies

Renal tubular disorders frequently present during routine laboratory investigation of children with failure to thrive. Tubular diseases can be isolated defects as in the case of distal renal tubular acidosis (RTA), or generalized defects as seen in Fanconi syndrome, and are primary or secondary in nature (Batlle and Haque, 2012). Tubulopathies such as renal glycosuria can result in solute wasting, and others such as Gordon syndrome result in excess solute reabsorption (O'Shaughnessy, 2015). Evaluation of patients with suspected tubular dysfunction begins with a careful history and physical examination focusing on a family history of renal or metabolic disease, and signs of failure to thrive, poor feeding, recurrent vomiting, dehydration, irritability, tetany, seizures, or icterus. The initial evaluation of patients with suspected tubular disease should include a complete blood count; a comprehensive metabolic panel including electrolytes, renal function, calcium, magnesium, and phosphorus; a venous or arterial blood gas; and urine for quantitative assessment of urine potassium, sodium, calcium, phosphorus, and magnesium excretion. In patients with suspected RTA, a metered urine pH should be obtained and urine sodium, potassium, and chloride concentrations to measure the urine anion gap. Additional testing including genetic testing should be based on the history and physical examination in combination with underlying metabolic disturbances. RTA is defined as an inappropriately elevated urine pH in the setting of metabolic acidosis. The **hallmark of RTA is hyperchloremic metabolic acidosis (normal anion gap acidosis);** the presence of metabolic acidosis must be confirmed by measurement of venous or arterial pH. In the setting of normal anion gap metabolic acidosis, a urine pH greater than 5.5 and an elevated urine anion gap are highly supportive of RTA (Carlisle et al., 1991).

Proximal RTA is defined by a decrease in the proximal tubule bicarbonate reabsorptive capacity, resulting in a low bicarbonate threshold with ensuing bicarbonate loss. Patients present with failure to thrive and hyperchloremic metabolic acidosis. However, patients with proximal RTA can reabsorb filtered bicarbonate below the lower resorption threshold. Thus patients with proximal RTA can maintain their serum bicarbonate level, although at a lower level than normal (typically 14 to 17 mEq/L). Because the distal tubule is intact, when the serum bicarbonate level is at or below the absorptive threshold of the proximal tubule, patients with proximal RTA can excrete urine with a pH less than 5.5. Isolated proximal RTA is rare and is more commonly seen in conjunction with Fanconi syndrome. Isolated proximal RTA can be caused by autosomal recessive mutations in the sodium bicarbonate cotransporter. Patients with this disorder usually have ocular defects, short stature, and intellectual impairment. Treatment of proximal RTA is challenging when exogenous alkali is not absorbed by the proximal tubule. Therefore, patients commonly require 10 to 15 mEq/kg/day of alkali with only modest improvement in serum bicarbonate levels.

Fanconi syndrome is a generalized disorder of the proximal tubule. **Patients with Fanconi syndrome typically present with failure to thrive, hyperchloremic metabolic acidosis with hypophosphatemia, and hypokalemia** (Moe et al., 2009). Typical urinary findings include glucosuria, aminoaciduria, and phosphaturia. Cystinosis is a common cause of Fanconi syndrome in children. It is an autosomal recessive disorder resulting in accumulation of free cysteine in intracellular lysosomes (Nesterova and Gahl, 2013). Presenting clinical features typically include polydipsia, polyuria, constipation, and failure to thrive. Many patients have evidence of rickets caused by renal phosphate wasting. Treatment of Fanconi syndrome is twofold; initially, the treatment of the underlying primary disease, if possible, and secondly, the replacement of urinary solute losses and the correction of acidosis.

Children with distal RTA present with short stature and failure to thrive, and they often have rickets. Classically, they have hyperchloremic metabolic acidosis, hypokalemia, hypercalciuria, and nephrocalcinosis. If the hypokalemia is severe, they may present with muscle weakness, cramps, and paralysis. The chronic metabolic acidosis results in bone demineralization. Patients with distal RTA are unable to excrete urine with a pH less than 5.5. Distal RTA may be either a primary or a secondary disorder. Primary distal RTA has been linked to autosomal dominant or autosomal recessive mutations in the basolateral Cl^-/HCO_3^- exchanger and autosomal recessive mutations in H^+-ATPase that are also associated with hearing loss. Secondary causes of distal RTA include medications and rheumatologic disorders. Distal RTA is treated by providing alkali equivalent to the amount of H^+ ion normally secreted by the distal nephron. Typically 3 to 5 mEq/kg/day of alkali is sufficient in most children to normalize the serum bicarbonate levels and correct the associated metabolic disturbances.

RTA associated with hyperkalemia is also known as type 4 RTA. It is associated with a number of disorders of either mineralocorticoid deficiency

or mineralocorticoid resistance. Decreased mineralocorticoid production is seen most commonly with 21-hydroxylase deficiency because Addison disease is rare in children. Angiotensin-converting enzyme inhibitor use can also result in functional hypoaldosteronism. Hyporeninemic hyperaldosteronism in children can be the result of drugs such as calcineurin inhibitors, nonsteroidal anti-inflammatory drugs (NSAIDs), and tubulointerstitial disease. Other common causes of type 4 RTA in children include obstructive uropathy and interstitial renal disease. In these disorders, aldosterone secretion is normal, but damage to the cortical collecting tubule results in functional resistance to aldosterone. Typically the degree of hyperkalemia is out of proportion to the severity of the renal insufficiency. Evaluation and management of type 4 RTA should be focused on defining the underlying etiology and treating the primary disease. Patients with glucocorticoid and mineralocorticoid deficiency should receive replacement therapy. Most cases of type 4 RTA caused by obstructive uropathy need urologic evaluation and surgery.

Dent disease is an X-linked recessive disorder characterized by low-molecular-weight proteinuria, nephrocalcinosis, recurrent urolithiasis, and progressive renal insufficiency. Dent disease results from a defect in the renal proximal tubule Cl^-/H^+ exchanger designated as CLC-5 (Devuyst et al., 2010). Patients with Dent disease have low–molecular weight proteinuria, not glomerular proteinuria (i.e., albumin). Treatment is directed at preventing renal calculi. Patients should have adequate fluid intake and eat a low-sodium diet. A thiazide diuretic may be helpful to decrease renal calcium excretion. ESRD usually occurs between the third and fifth decade of life.

Bartter syndrome is an autosomal recessive disorder, which usually presents in the first year of life with failure to thrive. Typically, patients have a prenatal history of polyhydramnios and prematurity, and polydipsia and polyuria as infants and young children. A history of constipation, salt craving, and muscle cramps are also quite common. **Hypokalemic metabolic alkalosis is the defining feature of Bartter syndrome** (Seyberth and Schlingmann, 2011). Blood pressure is typically normal, but plasma renin and aldosterone levels are elevated as a result of volume depletion. Bartter syndrome is commonly caused by mutations in the Na/K/2Cl cotransporter or in Barttin, which is associated with sensory neural deafness. Treatment of patients with Bartter syndrome is centered on replacement of urinary solute loss and management of polyuria.

Gitelman syndrome is an autosomal recessive disorder that also presents with hypokalemic alkalosis and can be confused with Bartter syndrome

(Seyberth and Schlingmann, 2011). Patients with Gitelman syndrome typically do not have failure to thrive, and there is no antenatal history of polyhydramnios. Hypomagnesemia is nearly universal in Gitelman syndrome, and urinary calcium excretion is low in Gitelman syndrome as opposed to Bartter syndrome, in which urinary calcium excretion is elevated. Many patients with Gitelman syndrome have a history of tetany and muscle cramps secondary to hypomagnesemia, which is an uncommon feature of Bartter syndrome. Gitelman syndrome is caused by mutations in the thiazide-sensitive NaCl cotransporter (NCC) found in the distal convoluted tubule. The keystone of treatment for Gitelman syndrome is magnesium and potassium supplementation to replace urinary loss.

Key Points

- The hallmark of RTA is hyperchloremic metabolic acidosis (normal anion gap acidosis).
- Children with distal RTA classically have hyperchloremic metabolic acidosis, hypokalemia, hypercalciuria, and nephrocalcinosis.
- Hypokalemic metabolic alkalosis is the defining feature of Bartter syndrome.
- RTA associated with hyperkalemia is also known as type 4 RTA.

Cystic Renal Disease

Cystic renal diseases are a common cause of both CKD and eventually ESRD in the pediatric population. Clinical presentation of these heterogeneous disorders is varied. Many patients are diagnosed prenatally or during the evaluation of hypertension, gross or microscopic hematuria, abnormal renal function, polyuria, or incidentally as part of an evaluation of abdominal pain or constipation. Often a specific diagnosis can be determined by imaging alone or by family history. However, genetic testing to achieve a definitive diagnosis is preferred. Currently there are no disease-specific treatment options that can alter disease progression or correct the underlying disorders. Therefore, therapy is conservative in nature and focused on management of complications that might accelerate CKD progression.

Multicystic dysplastic kidney (MCDK) disease appears on ultrasonography as a large reniform mass with noncommunicating cysts. The MCDK is nonfunctional and is usually unilateral; although rare, if MCDK is bilateral, neonatal mortality is nearly universal. Urologic anomalies are seen in up to 25% of patients with MCDK, including renal hypoplasia/dysplasia, vesicoureteral reflux, and ureteropelvic junction obstruction. Typically there is gradual reduction in the size of an MCDK with eventual involution over a period of months to years. The contralateral kidney typically shows compensatory hypertrophy. Because of the association of MCDK with VUR, voiding cystourethrography (VCUG) is recommended, particularly in patients with hydronephrosis and/or hydroureter. Serial monitoring of renal function, blood pressure, and renal ultrasonography is generally recommended at an interval of 3 months for the first year of life and then every 6 months up to involution, or at least up to 5 years. There is emerging data that patients with unilateral MCDK are at risk for development of early-onset hypertension and possible CKD. As a result, there is growing consensus that these patients should be monitored annually until well into adulthood.

Autosomal recessive polycystic kidney disease (ARPKD) is caused by a mutation in the *PKHD1* gene and occurs in approximately 1 : 40,000 live births (Bergmann et al., 2004). The kidneys are bilaterally enlarged as a result of fusiform cysts arising from the collecting ducts. The principal extrarenal manifestation of ARPKD is congenital hepatic fibrosis; over time, cystic dilation of the biliary tree develops with ensuing portal hypertension and liver failure. In addition to complications related to CKD, patients with ARPKD are at risk for ascending cholangitis, recurrent urinary tract infections, hypertension, nephrolithiasis, and bleeding from esophageal varices. Neonatal presentation with oligohydramnios/anhydramnios has a reported mortality rate of 25% to 50%. Over 75% of patients with ARPKD progress to ESRD by 5 years of age.

Autosomal dominant polycystic kidney disease (ADPKD) is caused by mutations in the polycystin-1 *(PKD-1)* or polycystin-2 *(PKD2)* gene, and it has a prevalence of roughly 1 : 1000 (Igarashi and Somlo, 2002; Torres et al., 2007). ADPKD usually presents in adulthood but can lead to clinical symptoms in older children and young adults. ARPKD is often identified in childhood either because of a positive family history, as an incidental finding on imaging for abdominal complaints (pain or constipation), or as part of an evaluation for hypertension or urinary tract infections. Similar to ARPKD, there is no disease-specific therapy approved in children. However, hypertension and urinary tract infections should be treated aggressively to limit disease progression. In patients with a family history of cerebral aneurysm, routine screening is currently not recommended in the pediatric population unless there are clinical signs or symptoms that warrant imaging.

Nephronophthisis in distinction to ARPKD or ADPKD is characterized by cyst formation at the corticomedullary junction, but the kidney size is typically normal. Most patients with nephronophthisis have a history of polyuria, polydipsia, anemia, and growth retardation, and eventually reach ESRD by early adolescence. Many forms of recessive nephronophthisis are syndromic in nature, and extrarenal manifestations are common; these include retinitis pigmentosa in Senior-Løken syndrome; cerebellar vermis aplasia and colobomas in Joubert syndrome; obesity, diabetes mellitus, and polydactyly in Bardet-Biedl syndrome; and skeletal dysplasias in Juene and Ellis-van Creveld syndromes. In patients with suspected recessive nephronophthisis, comprehensive genetic analysis is warranted as this can help to predict both complications and disease progression, and importantly can help with caregiver education. Currently there are more than 100 distinct genes that have been associated with nephronophthisis.

Other types of cystic kidney disease include **medullary cystic kidney disease,** which is an autosomal dominant disorder associated with hyperuricemia, gout, and ESRD in adults. Mutations in the gene encoding uromodulin/Tamm-Horsfall protein have been linked with one of the two types of medullary cystic kidney disease (type 2). In addition, glomerulocystic kidney disease is characterized by multiple small cortical cysts that result from cystic dilation of the Bowman space; the lack of tubular involvement distinguishes it from other forms of cystic disease. And medullary sponge kidney is a rare congenital cystic disorder in which there is ectasia of cortical ducts within the inner medulla of the kidney, resulting in a spongelike appearance on radiograph and is associated with nephrolithiasis and urinary tract infection.

Key Points

- Urologic anomalies are seen in up to 25% of patients with MCDK, including renal hypoplasia/dysplasia, VUR, and ureteropelvic junction obstruction.
- Autosomal recessive polycystic kidney disease (ARPKD) is caused by a mutation in the *PKHD1* gene.
- ADPKD is caused by a mutation in the polycystin-1 *(PKD-1)* or polycystin-2 *(PKD2)* gene.

Urolithiasis: Medical Management

Accurate data on the incidence and prevalence of urolithiasis in the pediatric population in the United States are not readily available. Although not as common as in the adult population, it is estimated that nephrolithiasis accounts for between 1 in 600 and 1 in 800 pediatric hospital admissions in the United States. Recent data suggest that the incidence of urolithiasis in the adolescent population has increased significantly over the past 10 years from roughly 20 per 100,000 in the late 1980s to more than 50 per 100,000 in 2014; this number is likely to be an underestimate as **urolithiasis remains under-diagnosed because many children are asymptomatic at the time of diagnosis** (Braun et al., 2016; Sas, 2011). Concurrent with the increase in the frequency of stone disease has been a shift in the types of stones seen at presentation. There has been a marked drop in the incidence of infectious stones from more than 60% before the 1980s to now less than 20%; there are similar reported reductions in the frequency of uric acid and ammonium acid urate stones. **The calcium stones are now the most prevalent.** The reasons behind these shifts are not clear, however in the United States, it has been proposed that changes in dietary practices, changes in types of fluids used for hydration, and the obesity epidemic underlie the rise in pediatric stone disease. Reported rates for stone recurrence in the pediatric population are variable, ranging from 15% to 20%, but may be as high as 30% in individuals with underlying metabolic disorders.

The clinical presentation of nephrolithiasis in children is varied and includes microscopic or gross hematuria, urgency, dysuria, frequency, hesitancy, and nonspecific abdominal or flank pain. Although increasingly less common in the United States, stones may be identified as part of the evaluation of urinary tract infections. It is not unusual for nephrolithiasis to be noted incidentally as part of a diagnostic evaluation for nonspecific complaints such as recurrent abdominal pain or failure to thrive. Children rarely present with the typical “renal colic” described in adults. In the United States, the majority of stones are found in the kidney, and presentation with bladder stones is more common in those with underlying urologic abnormalities.

Hypercalciuria is the most common risk factor identified in children with urolithiasis, and **the vast majority have idiopathic hypercalciuria.** Systemic hypercalcemia is less common and is associated with hyperparathyroidism, immobilization hypercalcemia, thyroid disease, idiopathic hypervitaminosis D, corticosteroid use, Williams syndrome, and rarely, mutation of the calcium-sensing receptor. Children with hypercalciuria are much more commonly normocalcemic, and with the exception of those on loop diuretics, most will have idiopathic hypercalciuria. There is, however, an increasing understanding of the genetic underpinnings of tubular dysfunction as a cause of hypercalciuria. Examples of this include mutations in *CLCN5* or *ORCL1* seen in Dent disease; mutations in *SLC12A1*, *KCNJ1*, *CLCNKB*, *BSND*, or *CASR* seen in Bartter syndrome; and mutations in *CLDN16* or *CLDN19* with familial hypomagnesemia with hypercalciuria and nephrocalcinosis.

Hyperoxaluria is a less common cause of urolithiasis and can be either primary or secondary. Secondary causes include enteric hyperoxaluria, excess vitamin C intake, and oxalate-rich diets. **Primary hyperoxaluria (PH)** is rare autosomal recessive disorder of oxalate metabolism of which there are three subtypes (Nazzal et al., 2016). PH type 1, which is the most common and most severe, is caused by aniline/glyoxylate aminotransferase (AGT) deficiency leading to increased systemic levels and excretion of glycolate and oxalate. PH type 2 is less common and is caused by mutations of glyoxylate reductase, leading to increased excretion of L-glycerate and oxalate. The clinical course of PH type 2 is usually less severe than in PH type 1. PH type 3 is the rarest and least severe form and is caused by mutations in *HOGA1*. Uric acid stones caused by hyperuricosuria can be either a primary disorder seen with inborn errors of purine metabolism (Lesch-Nyhan syndrome) or, more commonly, a secondary process associated with hematologic malignancies, gout, high purine intake, tubular disorders, or diabetes mellitus.

Other rare causes of pediatric urolithiasis include cystinuria and adenine phosphoribosyltransferase (APRT) deficiency. **Cystinuria** is a rare autosomal recessive disorder caused by mutations in either *SCL3A1* or *SLC7A9*, which result in decreased tubular reabsorption of cystine and other dibasic amino acids (ornithine, arginine, and lysine), leading to excessive excretion of cystine and stone formation. **APRT deficiency** is a rare autosomal recessive inborn error of adenine metabolism that results in the generation and urinary excretion of large amounts of poorly soluble 2,8-dihydroxyadenine with ensuing stone formation.

The evaluation of nephrolithiasis should begin with a history focused on symptoms associated with stones and predisposing factors including recurrent urinary tract infection, familial history of nephrolithiasis, gout, and conditions that increase enteric oxalate absorption: inflammatory bowel disease, short gut syndrome, or cystic fibrosis (Edvardsson et al., 2013). A through dietary history should be taken including sodium, calcium, fluid intake, and vitamin supplementation. Initial screening studies should focus on identifying a metabolic etiology for the kidney stones and should include serum electrolytes, blood urea nitrogen (BUN), creatinine, calcium, phosphorus, uric acid, and a venous blood gas (for evaluation of possible RTA). In the presence of hypercalciuria, hypercalcemia, or hypophosphatemia, serum parathyroid hormone and vitamin D levels should be obtained. Urine microscopy can be quite useful, particularly in the diagnosis of cystinuria or ARPT deficiency as the urinary crystals seen in these conditions are disease-specific. If the stone is available, it should be sent for analysis by infrared spectroscopy or radiographic diffraction. A urine culture should be done to rule out the presence of infection. Timed urine collections for calcium, oxalate, urate, citrate, and sodium should be performed for any child with stones if possible. For children in whom 24-hour urine collections are not feasible, spot ratios of urine solute to urine creatinine can be substituted. It is important to remember that normative data for urinary solute excretion vary with age. For example, a normal urine calcium-to-creatinine ratio for a 2-month-old child is in the 0.4 to 0.5 mg/mg range, and a ratio of 0.2 mg/mg is the upper limit of normal for a 5-year-old child. One of the primary goals of the initial evaluation is to identify patients with underlying metabolic disease for whom specific therapies will be beneficial and to determine which individuals are at risk for recurrent disease. In terms of imaging, to limit radiation exposure, ultrasonography is commonly employed in children for initial screening (Smith-Bindman et al., 2014). In patients with a nondiagnostic ultrasound examination, nonenhanced helical CT is highly sensitive and specific for the diagnosis of nephrolithiasis. Standard abdominal radiographs remain useful to determine stone burden and for longitudinal assessment of response to therapy. **Genetic testing is an increasingly important part of the evaluation of pediatric stone disease, as monogenic disorders may underlie urolithiasis or nephrocalcinosis in 20% of children.**

Medical therapy should be directed toward the underlying metabolic cause, if one has been identified, to prevent recurrence and growth of existing stones (Hernandez et al., 2015). **Increasing fluid intake with a minimum of 2 L/1.73 m^2/day** should be encouraged to decrease the chance of crystallization and growth of calculi.

With hypercalciuria, **salt restriction** will reduce urinary calcium losses by promoting reabsorption of sodium and calcium. Avoiding excessive protein intake to reduce the acid load is also recommended in recurrent stone formers. A thiazide diuretic can be used in the normocalcemic hypercalciuric patient to increase distal tubular reabsorption of calcium.

For primary hyperoxaluria, the goal of therapy is to decrease oxalate production, increase urine calcium oxalate solubility, and decrease crystal deposition in the kidney. Potassium citrate, orthophosphate, or magnesium citrate formulations are used to decrease urinary calcium oxalate supersaturation. A trial of pyridoxine should be given in PH type 1. About 20% of patients with PH type 1 will respond to pyridoxine treatment with normalization of urine oxalate concentration, and about 30% will have a partial response. However, pyridoxine is not effective in PH types 2 and 3 (Ben-Shalom and Frishberg, 2015). **Therefore, only successful liver transplantation can offer a potential cure for PH type 1.**

In individuals with hypocitraturia, a diet rich in fruits and vegetables, and/or supplemental potassium citrate is recommended. Sodium citrate should be avoided because the excess salt may increase hypercalciuria. In cystinuria, alkalization of the urine to a pH greater than 7.5 with potassium citrate will decrease cystine supersaturation. If stone formation continues despite high fluid intake and alkalinization of the urine, D-penicillamine or tiopronin can also be used. However, these medications are not always well tolerated. In hyperuricosuria, allopurinol, alkalinization of urine, and avoidance of protein excess are recommended. Struvite calculi often require surgical removal and prolonged treatment with antibiotics.

For children who present with acute renal colic, analgesia and adequate hydration with appropriate monitoring of fluid and electrolyte status are the mainstays of therapy. Radiologic evaluation should be performed, and in the setting of urinary obstruction, infection, acute kidney injury, or incontrollable pain, urologic intervention may be needed. For small ureteral stones (< 10 mm), management with observation with or without medical expulsive therapy is recommended. Urologic interventions such as ESWL, percutaneous nephrolithotripsy, ureteroscopy, and open surgery have all been successful therapies in children with urolithiasis. The choice of intervention is typically guided by stone size, composition, and location. Complete removal is important in children as residual small fragments are associated with regrowth and adverse outcomes. Medical expulsive therapy with an α-blocker has been successful in the management of small ureteral stones. ESWL is often employed for intermediate-size stones (10 to 20 mm) within the ureter or collecting system. Percutaneous nephrolithotomy is the recommended treatment for large renal pelvic or caliceal stones (>20 mm). Ureteroscopy is increasingly becoming a first-line procedure of choice, especially for distal ureteral stones greater than 10 mm. Open surgery is usually reserved for very young children with complex stones, children with orthopedic issues that limit positioning, or those who have failed primary therapy.

Urolithiasis has a high rate of recurrence, especially if an underlying metabolic disorder exists. Prevention with appropriate medical therapy and high fluid intake should be encouraged to limit morbidity. Long-term follow up is advisable as some children may develop CKD and progress to ESRD.

Key Points

- Urolithiasis remains underdiagnosed because many children are asymptomatic at the time of diagnosis.
- Calcium stones are now the most prevalent stones in children.
- Cystinuria results in decreased tubular reabsorption of cystine, ornithine, arginine, and lysine.

Hypertension

Hypertension in the pediatric population is defined as blood pressure on repeat measurements greater than the 95th percentile for age, gender, and height in comparison to normative population-based data. **The estimated prevalence of hypertension in children is much lower than the prevalence seen in the adult population; however, data suggests the increase in the prevalence in hypertension seen in the pediatric population in recent years is closely linked to increasing obesity rates in children** (Din-Dzietham et al., 2007, Falkner, 2010; Muntner, 2004). Weight-related disorders such as hypertension are now increasingly common in pediatric patients and are likely to account for the rise in the prevalence of hypertension from 2.7% noted in the early 1990s to 3.7% seen in the 2000s, with elevated blood pressures (previously known as prehypertension) observed in approximately 10% of children and adolescents.

An accurate measurement of blood pressure is essential to the diagnosis of hypertension (National High Blood Pressure Education Program, 2004). Accurate blood pressure measurement requires a cuff that is appropriate to the size of the child's upper arm; the bladder width should be at least 40% of the mid-arm circumference with a cuff length that covers at least two-thirds of the upper arm. Systolic blood pressure is defined by the first Korotkoff sound, with the disappearance of the Korotkoff sounds defining diastolic blood pressure. As accurate auscultatory measurement of blood pressure is often difficult in infants and young children, the use of automated (oscillometric) blood pressure measurement devices is now widespread; however it should be noted that pediatric normative blood pressure data is based on auscultatory and not oscillometric standards.

A recent clinical practice guidelines for management of hypertension in children and adolescents (Flynn et al., 2017) that was published by the American Academy of Pediatrics (AAP) update and refine reference data from the 4th Report of the National Institutes of Health Working Group for the management of blood pressure in children (2004). A major focus of this report was improving the recognition of hypertension by simplifying the initial screening blood pressure table. Furthermore, normative data by age, gender, and height have been revised, including only those children with a normal BMI. The blood pressure classification scheme has also been revised to align the classification system for adolescents with the absolute blood pressure values used in adult blood pressures guidelines (Redwine et al., 2012). **Current AAP guidelines now distinguish between children 1 to 13 years of age and adolescents older than 13 years of age, with normal blood pressure defined as less than the 90th percentile for children and less than 120/80 mmHg for adolescents** (Flynn et al., 2017). The term *prehypertension* has been abandoned and replaced with *elevated blood pressures* to be consistent with the adult guidelines.

Staging of hypertension is useful in determining which children require more immediate attention for diagnostic evaluation and management. In addition, staging can also predict the presence of end-organ damage from hypertension. Two other clinically relevant designations for severity of hypertension are important: (1) **hypertensive emergency**, when a patient has end-organ injury such as encephalopathy, pulmonary edema, or cerebral hemorrhage or clinical symptoms like blurred vision, headache, or nausea, which can be associated with severely elevated blood pressure; and (2) **hypertensive urgency**, when blood pressure is severely elevated without clear evidence of end-organ involvement or overt symptoms.

It also should be recognized that not every child with elevated blood pressure readings in the office setting has true hypertension. **Up to one-fourth of such patients have normal blood pressures outside of the office setting and are classified as having “white coat” hypertension.** The recent AAP care guidelines promote the **use of 24-hour ambulatory blood pressure monitoring (ABPM) in the evaluation of children and adolescents with suspected hypertension.** ABPM is not only useful in identifying patients with “white-coat” hypertension, but also it can identify individuals with so called “masked” hypertension: those with normal blood pressure readings in the office setting, but who are truly hypertensive. Furthermore, ABPM data is extremely useful in accessing effectiveness of antihypertensive regimens. Unfortunately, access to 24-hour ABPM is often limited and may require referral to pediatric subspecialists.

The causes of hypertension are classified as either **primary (essential)** or **secondary when a specific etiology is identified.** Historically, secondary causes of hypertension have been thought to predominate in the pediatric population (Vehaskari, 2009). However, with the rising rates of childhood obesity, the AAP guidelines have recognized that **primary (essential) hypertension is now the most common cause of hypertension in obese children older than 6 years of age with a positive family history of hypertension.**

Secondary causes of hypertension vary with age. In infants younger than 1 year of age, the majority of cases are caused by either coarctation of the aorta or renovascular disease. Renovascular disease may also present later in childhood. In school-age children, the dominant secondary causes of hypertension are renal parenchymal diseases including reflux nephropathy. Malignancy-associated hypertension, primarily with Wilms tumor and nephroblastoma, typically presents in infancy and early childhood, and pheochromocytoma is seen more frequently in the adolescent population. Secondary causes of hypertension should still be sought in adolescents, however, this population, much like adults, is far more likely to have primary (essential) hypertension.

Although hypertension is becoming more common in children, the differential diagnosis of childhood hypertension is quite broad. Features from the history, the physical, the age of the patient, and even the blood pressure values themselves can narrow the diagnostic focus. A secondary cause for hypertension should always be sought in infants younger than 1 year of age, and secondary causes should also be investigated thoroughly in preadolescent children as renal disease is the most common secondary cause of hypertension in this age group. The new AAP guidelines recognize that the **impact of obesity extends even into the early school-age population** as the previous guidelines recommended only a limited investigation into secondary causes of hypertension in patients older than 6 years of age with obesity, a strong family history of essential hypertension, and an unrevealing history and physical examination. Review of the patient's history should be focused on two areas; firstly, the presence of symptoms suggestive of hypertensive injury such as headaches, dizziness, diplopia, or vomiting; and secondly, information that provides insight into underlying causes of hypertension including neonatal history, urinary tract infections or unexplained fevers, signs and symptoms of renal or cardiac disease, chronic illness, medications, and family history of hypertension, kidney disease, early-onset cardiovascular disease, and diabetes.

The patient's weight, height, and growth percentiles should be defined. Ideally blood pressure measurements should be obtained in both upper extremities and in at least one lower extremity. The physical examination should focus on identifying signs of underlying disorders that are associated with hypertension.

Recommended initial diagnostic testing in all patients with confirmed hypertension includes a urinalysis, electrolytes, BUN, creatinine, and a lipid profile. Although commonly utilized, the current AAP guidelines do not recommend screening renal ultrasonography for patients older than 6 years of age unless there is an abnormal urinalysis or abnormal renal function. Additional testing such as renin and aldosterone levels; catecholamines; cortisol levels; genetic testing for forms of monogenic hypertension; or advanced imaging studies including VCUG, dimercaptosuccinic acid (DMSA) renal scans, CT angiography, magnetic resonance angiography (MRA), or angiography are often required based on an individual patient's clinical findings, initial screening studies, and the severity of the hypertension. Echocardiograms are no longer recommended as part of the initial screening of patients with confirmed hypertension. However, baseline echocardiography is now recommended at the initiation of pharmacologic therapy for all patients regardless of the etiology of their hypertension.

For patients with stage 1 hypertension or those with primary (essential) hypertension without end-organ damage, therapeutic lifestyle changes are the initial intervention of choice (Lurbe et al., 2009). There is clear data that support dietary modification (DASH diet), weight loss, and exercise in reducing blood pressure in children and adolescents. However, like all behavioral interventions, the long-term success of therapeutic lifestyle changes requires engagement not only of the patient, but of family members as well.

Pharmacologic therapy should be considered in patients with primary (essential) hypertension who do not have improvement in their blood pressure after a trial of therapeutic lifestyle changes, or in patients with stage 2 hypertension, evidence of end-organ damage, symptomatic hypertension, or secondary hypertension (Flynn and Daniels, 2006). Unlike adult hypertension guidelines, there are no data or evidence-based guidelines regarding which drug to select when initiating pharmacologic therapy. Acceptable first-line agents include diuretics, β-blockers, ACE inhibitors, ARBs, and calcium channel blockers. Rather than standardized approaches to pharmacologic therapy, most practitioners individualize therapy with the underlying renal, cardiac, or endocrine conditions guiding the choice of the initial agent. This would include the use of RAAS blockage for those with glomerulonephritis and other forms of CKD because of the additional benefit in terms of preventing CKD progression. Along similar lines is the use of RAAS inhibition in patients with type 1 or type 2 diabetes mellitus as these agents may slow or prevent the development of diabetic nephropathy. Conversely, the use of β-blockers in patients with asthma is not recommended. Adverse effects of each agent and available formulations need to be considered, because many standard adult hypertensive medications are not available in liquid formulations or are in fixed ratios that are not suitable for the pediatric population. Patients and families should be counseled about the potential side effects of the medications before initiation of therapy; this is especially important for adolescents who are engaged in organized sports and may be at risk for dehydration and acute kidney injury while on RAAS or diuretic therapy, and for sexually active adolescents on RAAS therapy regarding the potential for ACE fetopathy. Once therapy is initiated, blood pressure should be monitored closely, including laboratory monitoring, both for efficacy of the antihypertensive medication and for potential side effects. The goals of therapy for patients without diabetes or CKD have also been revised in the current AAP guidelines. Based on data suggesting that end-organ damage is present in patients with blood pressures greater than the 90th percentile but less than the 95th percentile, the current guidelines recommend **a target blood pressure goal of less than 90%, or less than 130/80 for adolescents.** Lower target goals are recommended for patients with CKD or diabetes mellitus (<50th percentile).

Key Points

- The increase in prevalence of pediatric hypertension in recent years is closely linked to increasing obesity rates in children.
- Up to one-fourth of patients have normal blood pressures outside of the office setting (“white coat” hypertension).
- Therapeutic lifestyle changes are the initial intervention of choice for patients with primary hypertension without end-organ damage.

Acute Kidney Injury

Acute kidney injury (AKI) is currently defined as an abrupt reduction in kidney function characterized by an absolute increase in serum creatinine of more than 0.3 mg/dL, a relative increase in serum creatinine of 50% from baseline, or 6 hours or more of oliguria (< 0.5 mL/kg/h of urine output). This precise definition is a result of a large body of work that recognized that AKI is a continuum renal injury wherein reductions in renal function are linked to adverse outcomes (Table 21.1 and Box 21.4) and shifts the focus to earlier detection and treatment of AKI before the development of significant morbidity, as noted in KDIGO staging table (Devarajan, 2013; Mehta et al., 2016; Selewski et al., 2014). Recent data suggest that the incidence of AKI is roughly 4 cases per 1000 pediatric hospital admissions, where as AKI is seen in up to one-third of all children admitted to intensive care units and one-half of pediatric patients with shock (Lameire et al., 2017). **Patients with AKI have been reported to have a nearly 15-fold increased mortality risk compared with patients without AKI (15% vs. 0.6%)** (Fitzgerald et al., 2016; Kaddourah et al., 2017). The estimated incidence of AKI requiring dialysis ranges from 1% to 2% in critically ill children (Slater et al., 2016; Sutherland et al., 2013). AKI can result from ischemic, toxic, or inflammatory mechanisms and can be further classified as caused by renal hypoperfusion (prerenal), structural injury to the kidneys (intrinsic), or urinary tract obstruction (postrenal). Primary renal disease is no longer the predominate cause of intrinsic AKI and has been supplanted by a heterogeneous mix of pathologic conditions including multiple organ failure, renal ischemia, nephrotoxic injury, congenital heart disease, bone marrow transplantation, and sepsis.

TABLE 21.1

KDIGO Criteria for Acute Kidney Injury

STAGE	SERUM CREATININE CHANGES	URINE OUTPUT CHANGES
I	SCr increase ≥0.3 mg/dL in 48 h or 1.5–1.9 times baseline	<0.5 mL/kg/h for 6–12 h
II	SCr increase 2.0–2.9 times baseline	<0.5 mL/kg/h for 12 h
III	SCr ≥3.0 increase or	< 0.5 mL/kg/h for 24 h

	SCr >4.0 mg/dL or If <18 years of age, estimated creatinine clearance <35 mL/min/1.73 m^2	or <0.3 mL/kg/h for 12 h

h, Hour; *KDIGO,* Kidney Disease Improvng Global Outcomes; *SCr,* serum creatinine.

Modified from Kellum JA, Lameire N; KDIGO AKI Guideline Work Group. Diagnosis, evaluation, and management of acute kidney injury: a KDIGO summary (Part 1). *Crit Care* 17(1):204, 2013.

Box 21.4

Causes of Acute Kidney Injury

Decreased true intravascular volume
  - Third-space losses: sepsis, trauma, burns, nephrotic syndrome
  - Gastrointestinal losses
  - Salt wasting: renal or adrenal
  - Diabetes insipidus: central or renal

Decreased apparent intravascular volume: congestive heart failure

Acute tubular necrosis/cortical necrosis
  - Hypoxic-ischemic insults
  - Medications: aminoglycosides, intravenous contrast agents, nonsteroidal anti-inflammatory drugs, chemotherapeutics
  - Exogenous toxins: ethylene glycol, methanol
  - Endogenous toxins: hemoglobin, myoglobin

Tumor lysis syndrome and uric acid nephropathy

Interstitial nephritis
  - Medication induced: anticonvulsants, antibiotics
  - Idiopathic

Glomerulonephritis: all causes

Vascular disorders
  - Hemolytic uremic syndrome
  - Renal artery or vein thrombosis

Infection
  - Pyelonephritis
  - Sepsis

Obstructive lesions
  - Obstructed single kidney
  - Bilateral ureteral obstruction

- Urethral obstruction

The diagnosis of AKI is dependent on increases in serum creatinine compared with baseline levels. As opposed to the adult population, normal serum creatinine levels vary in the pediatric population based on age, muscle mass, and body size; therefore there is no absolute creatinine level that defines pediatric AKI. Typically renal function needs to decrease by 50% before a change in serum creatinine can be measured, and changes in creatinine commonly lag behind the reduction in renal function (GFR) by 24 to 72 hours. This lack of sensitivity and delayed response has presented challenges to early identification of patients with AKI. A number of biomarkers to identify early AKI have been developed; these include neutrophil gelatinase-associated lipocalin (NGAL), kidney injury molecule-1 (KIM-1), and interleukin-18. Although there is substantial data in the adult population regarding the sensitivity and specificity of these biomarkers, and although there are emerging pediatric data, these biomarkers have not yet entered widespread clinical use, and the application of the data from adult studies is challenging in the pediatric population.

Differentiating between functional and intrinsic AKI is essential. **Functional AKI** is a sodium-avid state with maximal reabsorption of solutes and water by the intact proximal tubule; on the other hand, the tubular damage typical of **intrinsic AKI** results in impaired reabsorptive capacity of the proximal tubule. Functional AKI is typically characterized by fractional excretion of sodium (FE_{Na}) less than 1%, and greater than 3% is characteristic of intrinsic AKI. However, the use of FE_{Na} in patients on diuretic therapy is unreliable. In this setting, the fractional excretion of urea (FE_{Urea}) is very useful, with FE_{Urea} less than 35% being indicative of prerenal AKI.

AKI results in the disruption of normal electrolyte and fluid homeostasis. Common complications include **hyponatremia** caused by excessive free water retention, **hypernatremia** from sodium administration, **hyperkalemia** caused by reduction in glomerular filtration and tubular potassium secretion, **anion gap metabolic acidosis** secondary to impaired renal hydrogen ion excretion and concurrent impairment of bicarbonate reabsorption and regeneration, **hyperphosphatemia** caused by reduced renal excretion, and **hypocalcemia** secondary to increased serum phosphate and impaired vitamin D metabolism. Fluid overload in patients with AKI is challenging as adequate fluid resuscitation is essential for tissue perfusion in patients with prerenal AKI. However, there is a clear association between excessive fluid accumulation and adverse outcomes in the pediatric population.

Prerenal AKI requires prompt and vigorous fluid resuscitation with isotonic fluids. The use of potassium-containing fluids should be avoided until urine output is established and the severity of AKI is defined. If oliguria is present, conservative fluid management should be instituted. Fluid intake should therefore be limited to match output including insensible fluid loss with replacement of output. If patients are fluid overloaded, then urine output should not be replaced, and diuretics are likely indicated. If adequate urine output cannot be achieved with diuretic therapy, RRT may be required. In addition, aggressive nutritional support is essential for all patients with AKI (Kyle et al., 2013). Adequate calories should be provided that meet maintenance requirements and to limit or prevent excessive catabolism. Protein intake should not be restricted. If adequate nutrition cannot be achieved because of fluid restriction, early institution of RRT should be considered. Nephrotoxic agents should be avoided in AKI, as they may worsen the injury or delay recovery of function. Medications should be adjusted based on residual renal function. Importantly, patients in the early phase of AKI should be assumed to have a GFR of less than 15 mL/min/1.73 m^2, regardless of the absolute value of the serum creatinine.

Indications for initiating RRT in AKI typically include fluid overload that is unresponsive to diuretics, the need to deliver adequate nutrition, or to address hyperkalemia or metabolic disturbances that are refractory to medical therapy, and symptomatic uremia. RRT options include hemodialysis, peritoneal dialysis, and continuous renal replacement therapy (CRRT). The choice of dialysis modality depends on the patient's clinical status, the available clinical expertise, and the availability of appropriate resources. Hemodialysis provides the most efficient and rapid correction of fluid and electrolyte disturbances; however hemodialysis can be poorly tolerated in patients with hemodynamic instability. Therefore, **CRRT via hemodialysis has become the standard of care as it delivers slow continuous correction of fluid overload and electrolyte imbalances.** Peritoneal dialysis is also a CRRT modality and has been preferred in neonates and small infants when central venous access can prove challenging. The advantages of peritoneal dialysis include ease of performance and avoiding the requirement for specialized equipment, personnel, or anticoagulation. In critically ill children with respiratory failure, dwell volumes in the peritoneal cavity may be poorly tolerated, and previous abdominal surgery with compromise of the peritoneum, intra-abdominal infection, and ostomy placement can limit the application of peritoneal dialysis.

Data suggest that **children who have recovered from an episode of AKI are at significant risk for CKD,** as more than one-third have been reported to have either reduced kidney function or were dialysis-dependent on hospital discharge. Furthermore, nearly two-thirds of the patients with long-term follow-up had evidence of CKD. These data suggest that long-term follow-up is warranted for children who survive an AKI episode.

Key Points

- Hospitalized pediatric patients with AKI have a nearly 15-fold increased mortality risk compared with patients without AKI.
- Prerenal AKI requires prompt and vigorous fluid resuscitation with isotonic fluids.
- CRRT via hemodialysis has become the standard of care as it delivers slow continuous correction of fluid overload and electrolyte imbalances.

Chronic Kidney Disease

CKD is defined by the persistence of structural or functional abnormalities of the kidney for more than 3 months. The primary marker of kidney damage using the Kidney Disease Outcomes Quality Initiative (KDOQI) staging system is a decrease in GFR. This staging system was developed to stratify the severity of CKD and to guide clinical management, as the complications of CKD commonly develop at specific GFR levels irrespective of the etiology of CKD. There are a number of caveats with respect to applying this system to pediatrics. First, the staging of CKD excludes patients younger than 2 years of age. A normal term infant has a GFR of approximately 40 mL/min/1.73 m^2, and, as part of normal renal developmental processes, GFR does not reach final adult levels until nearly 2 years of age, thus GFR increases during the first 2 years of life can make definitive CKD staging in patients younger than 2 years of age problematic. Secondly, the requirement for renal abnormalities to persist for more than 3 months to meet the criterion for CKD makes this staging system inapplicable to newborns and infants younger than 3 months of age.

Causes of CKD in children are very different from those in adults and vary by age group within the pediatric population. In younger children, the most common causes are CAKUT: renal hypoplasia/dysplasia and obstructive lesions such as posterior urethral valves and prune belly syndrome. Renal cystic diseases, including multicystic kidneys, cystic renal dysplasia, juvenile nephronophthisis, and autosomal recessive polycystic kidney disease, are also common causes of CKD during childhood. Glomerular diseases such as nephrotic syndrome, focal segmental glomerulosclerosis, hemolytic uremic syndrome, membranoproliferative glomerulonephritis, membranous nephropathy, and lupus nephritis are uncommon causes of CKD in early childhood, but by late childhood and early adolescence, they become the predominant causes of CKD. Although the prevalence of ESRD, including renal transplantation and chronic dialysis, is well-defined, no incidence or prevalence data for pediatric CKD are available from North American registries.

The frequency and severity of the complications of CKD increase as CKD progresses. The classification of CKD is based on five stages (Table 21.2), and stage-based care guidelines for the management of these complications are detailed in consensus recommendation by the KDOQI and KDIGO initiatives (Inker et al., 2014; KDIGO, 2009; KDOQI, 2009).

TABLE 21.2

Classification of Chronic Kidney Disease for Children Older Than 2 Years of Age

STAGE	DEFINITION	GFR (mL/min/1.73 m^2)
I	Normal or ↓ GFR (with kidney damage)	≥90
II	Mild ↓ GFR (with kidney damage)	60–89
III	Moderate ↓ GFR	30–59
IV	Severe ↓ GFR	15–29
V	Kidney failure	<15 or dialysis

GFR, Glomerular filtration rate.

Protein malnutrition is seen in up to 20% of pediatric patients with any stage of CKD and is more common in advanced CKD and in infants and younger children. In younger children, the key factor contributing to malnutrition is inadequate intake. Although the underlying cause of malnutrition in children with CKD is often multifactorial, it is extremely important that this be recognized and treated promptly and aggressively, as malnutrition has been strongly associated with mortality. Children with CKD often have an impaired appetite, and this can be further complicated by nausea and vomiting. They may also require the restriction of specific dietary components, especially potassium and phosphate. Specialized formulas and diets designed for children with CKD are often required. A pediatric dietitian with experience in CKD/ESRD is essential to optimize caloric intake, which is the overriding treatment goal for malnutrition in children with CKD.

Growth impairment is a common complication in children with CKD and can have a major psychological impact on a child while negatively affecting their quality of life (QoL). Children with CKD are approximately 1.5 standard deviations below normal for height, and this height deficit is greatest in the youngest children. With aggressive treatment of nutritional deficiencies and renal osteodystrophy, a normal growth pattern is usually reestablished until the child reaches ESRD (CKD stage V). The causes of growth delay in children with CKD include malnutrition/protein-energy wasting, chronic acidosis, severe renal osteodystrophy, sodium depletion, and growth hormone resistance. Where possible, treatment should be directed to correction of these metabolic disturbances before the introduction of growth hormone (Haffner et al., 2000). Children with CKD are not growth hormone deficient, but rather have abnormalities along the growth hormone activation pathway including reduced production of insulin-like growth factor-1 (IGF-1), increased circulating levels of IGF-binding proteins that reduce IGF-1 activity, and resistance of bone to growth hormone activity. Despite the consensus recommendations for children with growth impairment and CKD, only about 1 in 4 children are prescribed recombinant growth hormone.

CKD/mineral bone disease, a term now employed to replace *renal osteodystrophy,* is a systemic disorder characterized by alterations in mineral metabolism, bone deformities, and calcific cardiovascular abnormalities in CKD. Insufficiency of $1,25(OH)_2$ vitamin D in CKD can be a result of deficient activation of cholecalciferol to the active form of 1,25-dihydrocholecalciferol in the kidney or a result of low cholecalciferol levels as a result of dietary insufficiency. In the later stages of CKD, retention of phosphate worsens as renal function declines. Both the elevation of phosphate levels in plasma and a fall in plasma calcium values stimulate parathyroid hormone secretion; the parathyroid hormone then increases phosphate excretion by the suppression of tubular phosphate reabsorption, thereby returning phosphate values to normal but at the expense of persistently elevated parathyroid hormone values. It has been shown that skeletal mineralization defects start in pediatric patients as early as CKD stage II, even before defects of bone turnover or any biochemical abnormality, except for an increase in circulating FGF-23 levels. The effects of metabolic bone disease on the epiphysis are unique to children with CKD and include growth failure, slipped epiphysis, and rickets.

There are a number of therapeutic approaches to prevent and treat renal bone disease in patients with CKD. Initially, if plasma levels of 25-OH vitamin D are low, then vitamin D_3 (cholecalciferol) supplements should be prescribed. Calcitriol (Rocaltrol), active 1,25 vitamin D, is typically prescribed if the parathyroid hormone levels exceeds the recommended limits and the calcium level is not elevated. In the presence of elevated plasma phosphate values, if dietary phosphate restriction is ineffective, phosphate binders such as calcium carbonate, calcium acetate, or sevelamer should be prescribed. Calcium-containing compounds are available in liquid formulations and, therefore, are most easily used in young children. However, excessive total calcium ingestion may lead to hypercalcemia, which has been associated with vascular calcification, even in children.

Multiple studies have evaluated QoL and social behavior in children with CKD and have **shown lower health-related QoL scores when compared with healthy controls and other children with chronic medical conditions;** in fact, patients with CKD/ESRD have lower QoL scores than children with cancer. Children with CKD are also at risk for neurocognitive impairment. Developmental problems have been reported in as many as 25% of infants with renal disease and correlates with the severity of renal dysfunction. Cognitive deficits are also noted in older children, and the overall IQ of school-age children with CKD is lower than the normal population.

Anemia is nearly universal in advanced CKD. **The most common cause of anemia with CKD is a deficiency of erythropoietin.** However, erythropoietin deficiency in CKD is often confounded by other causes of anemia including iron deficiency, blood loss associated with surgical procedures, and frequent phlebotomy. Erythropoietin-stimulating agents are essential for the management of the anemia in all CKD patients and especially in pediatric CKD patients (Kliger et al., 2013). Either epogen or darbepoetin can be used to successfully treat anemia in the vast majority of children with CKD. Iron therapy is also required for nearly all children with CKD, however iron therapy is affected by gastrointestinal side effects, and there is decreased absorption with concomitant use of phosphate-binding agents or proton pump inhibitors.

Children with CKD are in the highest risk category for cardiovascular disease, and registry data indicates that cardiovascular disease accounts for nearly one-half of all deaths of children on dialysis. Contributing risk factors include chronic hypertension, dyslipidemia, and abnormal mineral metabolism. Hypertension has been reported in more than one-half of children with CKD, and, even with antihypertensive medications, less than 50% were well controlled (ESCAPE Trial Group et al., 2009; Mitsnefes, 2012; Taler et al., 2013). Left ventricular hypertrophy is common in children with CKD, with nearly 60% to 80% of children who are initiating dialysis having left ventricular hypertrophy as well. Dyslipidemia is also seen in approximately 39% to 65% of children with CKD. The most common abnormality is hypertriglyceridemia, followed by elevated non-HDL cholesterol and lower HDL cholesterol levels. It is estimated that one-fourth of children have more than one lipid abnormality. Initial treatment options usually involve nutrition and dietary modification (Sarnak et al., 2015).

Electrolyte abnormalities in children with CKD are very common and include metabolic acidosis from renal tubular dysfunction and/or progressive uremia with ensuing retention of phosphate or sulfate anions. Treatment consists of correction of the acidosis with supplemental bicarbonate or citrate solutions and is particularly important for growth and bone health.

Hyponatremia may also occur as a result of urinary sodium wasting and is commonly seen in the setting of CKD associated with CAKUT. Hyperkalemia is frequently seen as a result of impaired renal potassium excretion and can be aggravated by concurrent metabolic acidosis; potassium control is often focused on dietary restriction and modification.

The natural course of CKD is gradual deterioration of kidney function. **This decline does not occur in a linear fashion as the later stages of CKD are associated with a more rapid progression.** Although there are no clear therapeutic interventions to prevent or reverse progression of CKD, several factors have been identified that may slow progression. In adults, intake of a reduced protein diet may reduce proteinuria and slow the decline of kidney function. However pediatric trials have shown that lower protein intake does not provide any benefit as measured by the rate of decline in creatinine clearance over a 2-year period. Therefore, it is not recommended to restrict protein intake in pediatric patients with CKD unless evaluation of an individual's diet or laboratory values suggests that their protein intake is clearly excessive. Strict blood pressure control is the only intervention that has been shown to decrease progression of CKD in children. Based on this, KDIGO guidelines recommend that the target blood pressure for children should be the 50th percentile for age, gender, and height, and particularly if children have proteinuria. Children with obstructive uropathies, particularly those with inadequate bladder emptying including those who require intermittent catheterization, as well as increasing hydronephrosis, which may indicate partial lower tract obstruction, should be dealt with promptly by a pediatric urologist. Similarly, for those with repeated urinary tract infections, efforts should be focused on prevention either by assuring appropriate bladder drainage or by using prophylactic daily antibiotics.

Key Points

- Causes of CKD in children are very different from those in adults and vary by age group within the pediatric population.
- The most common cause of anemia with CKD is a deficiency of erythropoietin.
- With CKD, kidney function declines in a nonlinear fashion as the later stages are associated with a more rapid progression.

End-Stage Renal Disease: Dialysis and Renal Transplantation

ESRD is defined by the need for either chronic dialysis or kidney transplantation to sustain life. There is no absolute creatinine or BUN level that mandates the initiation of chronic dialysis. **Typically initiation of dialysis is considered in children who have reached CKD stage V (GFR <15 mL/min/1.73 m^2) or when CKD is complicated by uncontrolled hypertension, volume overload, metabolic derangements, poor growth, or complications of uremia** (Greenbaum and Shaefer, 2012). There are two chronic dialytic modalities available for infants, children, and adolescents: **peritoneal dialysis** and **hemodialysis** (Chand et al., 2017; Fischbach et al., 2005). Selection of hemodialysis or peritoneal dialysis is dependent on a number of factors including the needs of the patient and family, patient size, age, lifestyle choices, and psychosocial risk.

Peritoneal dialysis is the most common initial modality for children younger than 9 years of age and less than 20 kg, as the treatment is provided at home and does not require central venous access. For older children, it offers the advantage of greater flexibility in the timing of treatments and better social integration. PD can be successfully performed in many patients with prior urologic surgeries including vesicostomies, however the presence of omphalocele, gastroschisis, diaphragmatic hernia, or bladder exstrophy are contraindications to peritoneal dialysis.

Peritoneal dialysis is performed via a process of repeated instillation and drainage of dialysis solution both into and out of the peritoneal space via a surgically implanted peritoneal dialysis catheter. The dialysate solutions contain electrolyte additives in physiologic concentrations, with the exception of potassium and phosphorus, to facilitate correction of electrolyte abnormalities and acid-base abnormalities. The glucose concentration in the dialysis solution creates an osmotic gradient that mediates the net movement of water into the peritoneal cavity, which is referred to as *ultrafiltration*. In peritoneal dialysis, solute clearance occurs via a process of diffusion whereby solutes move from a compartment of higher concentration to a compartment of lower concentration across the peritoneal membrane and by convection whereby solutes move via solvent drag with the movement of fluid between the blood and dialysate compartments. Peritoneal dialysis is typically performed overnight for 8 to 12 hours and thus achieves more steady metabolic and blood pressure control than hemodialysis. Peritoneal dialysis can be prescribed either manually (continuous ambulatory peritoneal dialysis) or using an automated machine (continuous cycling peritoneal dialysis). Continuous cycling peritoneal dialysis is prescribed for the majority of pediatric patients in the United States. The peritoneal dialysis prescription, including volumes, dwell times, and dextrose concentration, is tailored to each child's specific needs.

Infections, such as peritonitis and tunnel infections, are the most common complications of peritoneal dialysis (Warady et al., 2012). Peritonitis typically occurs more frequently in younger children. Peritonitis typically presents with acute onset of abdominal pain and cloudy dialysis fluid, and fluid with a white blood cell count greater than $100/mm^3$ and at least 50% neutrophils meet the presumptive criteria for peritonitis. Gram-positive organisms are the most common cause of peritonitis in the pediatric population, followed by culture-negative, and then gram-negative organisms. Fungal peritonitis, although rare, can require discontinuation of peritoneal dialysis, and transition to hemodialysis. Peritonitis can lead to the development of intra-abdominal adhesions, and ultimately peritoneal membrane failure. Peritoneal dialysis catheter exit site and tunnel infections are also important risk factors for peritonitis and can require catheter removal if persistent or recurrent. Noninfectious complications of peritoneal dialysis include the development of dialysate leak, abdominal hernias, hydrothorax, or hemoperitoneum.

In children older than 10 years of age, hemodialysis is the predominant chronic dialysis modality in the United States. As opposed to peritoneal dialysis, hemodialysis requires chronic central venous access. The ability to maintain hemodialysis access in infants and smaller children presents a major challenge for pediatric ESRD care. Options for hemodialysis access include arteriovenous fistula; arteriovenous graft, which uses a synthetic material to create a conduit between an artery and a vein; and central venous hemodialysis catheters. Arteriovenous fistulas have better survival rates and lower rates of infection compared with arteriovenous grafts or hemodialysis catheters and are recommended for children greater than 20 kg for whom renal transplantation is not eminent (Ma et al., 2013). However arteriovenous fistulas are not always technically possible, particularly in younger children for whom a central hemodialysis catheter may be necessary. Hemodialysis catheters are preferentially placed in the internal jugular veins; the subclavian veins should be avoided because of the risk for subclavian stenosis.

Hemodialysis removes metabolic waste products, solutes, and excess fluid via diffusion, convection, and ultrafiltration. Diffusion characterizes the solute movement across the semipermeable dialysis membrane against a concentration gradient. Convection is the movement of solutes with plasma water; it is determined by the amount of ultrafiltration and characteristics of the dialysis membrane. Ultrafiltration is the movement of water across the dialysis membrane by convective flow caused by a pressure or osmotic gradient. Hemodialysis fluid removal is determined by the transmembrane pressure gradient across the dialysis membrane and the permeability of a given dialysis membrane to water, and the dialysate solution contains electrolytes in physiologic concentrations to normalize electrolytes and correct acid-base abnormalities. Typically, pediatric patients receive in-center hemodialysis 3 to 4 times per week for 4 hours at a time to achieve adequate metabolic control and fluid balance. Home hemodialysis is also an option for select patients and caregivers; similar to peritoneal dialysis, home hemodialysis is provided daily at night to provide more consistent metabolic control and fluid balance than achieved with the thrice-weekly in-center hemodialysis treatments (Hothi et al., 2016).

For the vast majority of pediatric patients with ESRD, the ultimate treatment goal is renal transplantation, not long-term dialysis. Pediatric patients younger than 18 years of age account for less than 5% of all kidney transplantations performed in the United States (Dharnidharka et al., 2014; Lau et al., 2012; United States Renal Data System [USRDS], 2016). Of the approximately 900 annual pediatric kidney transplants, about two-thirds are from deceased donors and one-third are from living donors (primarily parents). For patients with an identified living related donor, a preemptive transplant before the need for dialysis is often recommended. The transplant community has recognized the **unique benefits that renal transplantation has for pediatric ESRD patients, including improved growth, neurocognitive development, and QoL.** Therefore, children on the transplant waiting list for deceased-donor organs before 18 years of age receive priority compared with the average adult deceased-donor transplantation candidate. Furthermore, children are also preferentially allotted kidneys from younger donors in an attempt to optimize the life of the allograft. Overall outcomes for pediatric kidney transplants are excellent, with 50% of deceased-donor transplants functioning 12.5 years post-transplant and 50% of living-donor kidneys functioning 20 years post-transplant.

Almost all children with ESRD should be considered for kidney transplantation; absolute contraindications are few but include active malignancy or uncontrolled infections. Cognitive impairment or intellectual disability should not automatically exclude a patient from consideration of kidney transplantation (Goldberg et al., 2015).

There are a number of unique considerations relating to renal transplantation in the pediatric population. In infants, because of technical issues and the increased risk for graft thrombosis, **many centers wait until the child is at least 10 kg and 65 cm in length before proceeding with transplantation.** As CAKUT is a common cause of ESRD in the pediatric population, urinary tract repair or reconstruction of anomalies needs to be addressed before transplantation to optimize outcomes. Compared with adults, immune-mediated glomerular disease and focal segmental glomerulosclerosis are common causes of ESRD in children, thus the risk for disease recurrence in the allograft must be considered both in terms of pretransplant evaluation and postoperative care. This is particularly of concern for primary focal segmental glomerulosclerosis, membranoproliferative glomerulonephritis, C3 glomerulopathy, and atypical hemolytic uremic syndrome. Adequate immunization before renal transplant is also a necessity. Surgical removal of native kidneys is often considered in the peritransplant period; indications for nephrectomy include chronic or recurrent pyelonephritis, hypertension refractory to medical therapy, and uncontrolled nephrotic syndrome.

For most children less than 20 kg, the allograft is placed intra-abdominally and anastomosed to the aorta and the inferior vena cava. For children more than 20 kg, a retroperitoneal approach is used with the allograft placed in the iliac fossa and vascular anastomoses to the common or external iliac vessels. An antirefluxing anastomosis for the donor ureter into the recipient bladder is common as this will reduce the risk for vesicoureteral reflux into the allograft. The use of ureteral stents at the time of transplantation to reduce the risk for ureteral obstruction appears to be largely center-specific.

In the immediate post-transplant period, primary graft dysfunction is reported to occur in less than 3% of pediatric kidney allografts, with delayed graft function requiring dialysis being reported in 5% of pediatric related living-donor allografts and 15% of pediatric deceased-donor allografts.

Immunosuppression, both in terms of induction at the time of transplantation and chronic maintenance therapy, are needed for long-term function of the allograft. Most pediatric transplant centers now use antibody-based agents such as thymoglobulin or basiliximab at the time of transplantation for induction therapy. Thereafter, children are typically maintained on long-term immunosuppression with a calcineurin inhibitor (tacrolimus or cyclosporine) and an antiproliferative agent such as mycophenolate mofetil. In the past decade, there has been a reduction in the use of steroids as part of maintenance therapy, with many centers adopting steroid-free maintenance immunosuppression for children thought to be at lower immunologic risk for rejection.

Infectious complications are a concern in all transplant recipients, particularly in younger children who may not yet have acquired native immunity to cytomegalovirus (CMV), Epstein-Barr virus, or the BK virus. Transplant centers commonly use valganciclovir as prophylaxis to reduce the risk for CMV disease. Trimethoprim-sulfamethoxazole is often used for prophylaxis against *Pneumocystis carinii* pneumonia early in the post-transplant period. However, chronic immunosuppression also increases the risk for renal cell carcinoma, thyroid carcinoma, and cutaneous malignancies by nearly sevenfold in transplant recipients compared with the general pediatric population.

In the pediatric renal transplant population, the risk for acute cellular rejection in the first year post-transplant is less than 10% in living-donor transplants and approximately 15% in deceased-donor transplants. Generally the rates of acute rejection decrease over the life of a renal allograft. Although most rejection episodes are reversible, rejection episodes negatively affect long-term graft function. Antibody-mediated rejection is increasingly being recognized as a cause of allograft dysfunction. The impact on antibody-mediated rejection on long-term allograft function and the treatment strategies for antibody-mediated rejection are areas of ongoing investigation; many centers are now using a combination of therapies for antibody-mediated rejection including intravenous immunoglobulin, rituximab, and/or apheresis. Over time, all transplants will lose substantial function as a result of a process-labeled chronic allograft nephropathy for which there is no current therapeutic intervention. With this progressive decline in allograft function, nearly all pediatric renal transplant recipients will eventually require either retransplantation or a return to dialysis.

Key Points

- Peritoneal dialysis is the most common initial modality for dialysis in children younger than 9 years of age and less than 20 kg.
- The unique benefits of renal transplantation include improved growth, neurocognitive development, and QoL.
- The risk for acute cellular rejection in the first year after pediatric renal transplantation is less than 10% in living-donor transplants.
- The risk for acute cellular rejection in the first year post-transplant is approximately 15% in deceased-donor transplants.

Summary

Effective partnership between pediatric urologists and pediatric nephrologists is needed for the optimal care of pediatric patients with kidney and urinary tract abnormalities. Although differences in opinion regarding best approaches may exist, a careful appreciation of the expertise of both specialties is needed, as both have expert teams of health care providers that can provide the full spectrum of care for these complex issues. As a result of these specialties working closely together, the management of these disorders has clearly improved to provide future generations of children with improved health and less burden from their kidney and urinary tract diseases.

Perinatal Urology

C.D. Anthony Herndon MD, FAAP, FACS, Rebecca S. Zee MD, PhD

Urinary tract dilation (UTD) represents the second most common anomaly detected during prenatal screening following cardiac defects and occurs with a frequency of 1% to 3%. (Nguyen et al., 2010). A majority of UTD cases are detected in the second trimester, which affords the opportunity for parental counseling in a setting that occurs well before delivery (Pathak and Lees, 2009). Discussions may include recommendations for postnatal evaluation and management or referral to centers of excellence when uncommon conditions such as lower urinary tract obstruction (LUTO) or bladder exstrophy are suspected. Although a majority of conditions such as transient dilation, ureteropelvic junction obstruction (UPJO) pattern of dilation, and vesicoureteral reflux (VUR) will not lead to surgical intervention, a subset of patients are at increased risk for urologic disease; thus clinical thresholds for the recommendation for prophylactic antibiotics (PA), lower urinary tract imaging, and more invasive upper tract imaging should be appreciated (Lee et al., 2006). The aim of this chapter is to provide a comprehensive overview of care for the patient with perinatal UTD inclusive of: grading systems utilized by providers, prenatal consultations for specific conditions and role for intervention, imaging modalities and indications, differential diagnosis with expected outcomes, a risk stratification system used for recommendation of postnatal evaluation and management, and urologic perinatal emergencies.

▶Videos 22.1, ▶22.2, and ▶22.3 demonstrate prenatal urinary tract dilation of the fetal kidney, fetal measurement of amniotic fluid index, and fetal ultrasonography documenting multicystic dysplastic kidney (MCDK).

Prenatal Imaging

Maternal-Fetal Ultrasound

Although fetal metanephric kidney begins at the 28th day of gestation, urine production begins in earnest at 14 weeks' gestation and can be detected on prenatal ultrasonography (Park, 2016). The American College of Obstetricians and Gynecologists (ACOG) recommends that the initial screening ultrasonography be performed between 18 and 20 weeks' gestation (ACOG, 2009). **In the United States, the initial fetal screening ultrasonography is performed around 20 weeks' gestational age, with an average of two scans for low-risk pregnancies and four scans for high-risk pregnancies** (Siddique et al., 2009)**. Ultimately, the exact timing is left to the discretion of the physician.** There are no set criteria for referral to a maternal-fetal medicine specialist, but increasing degrees of urinary tract dilation and/or an abnormal amniotic fluid index (AFI) should prompt referral. **The AFI is an assessment of amniotic fluid that should include the cumulative measurement of 4 pockets of fluid** (Fig. 22.1)**. Normal AFI is 8 to 18, oligohydramnios is less than 5 or 6, and polyhydramnios is 20 to 24.**

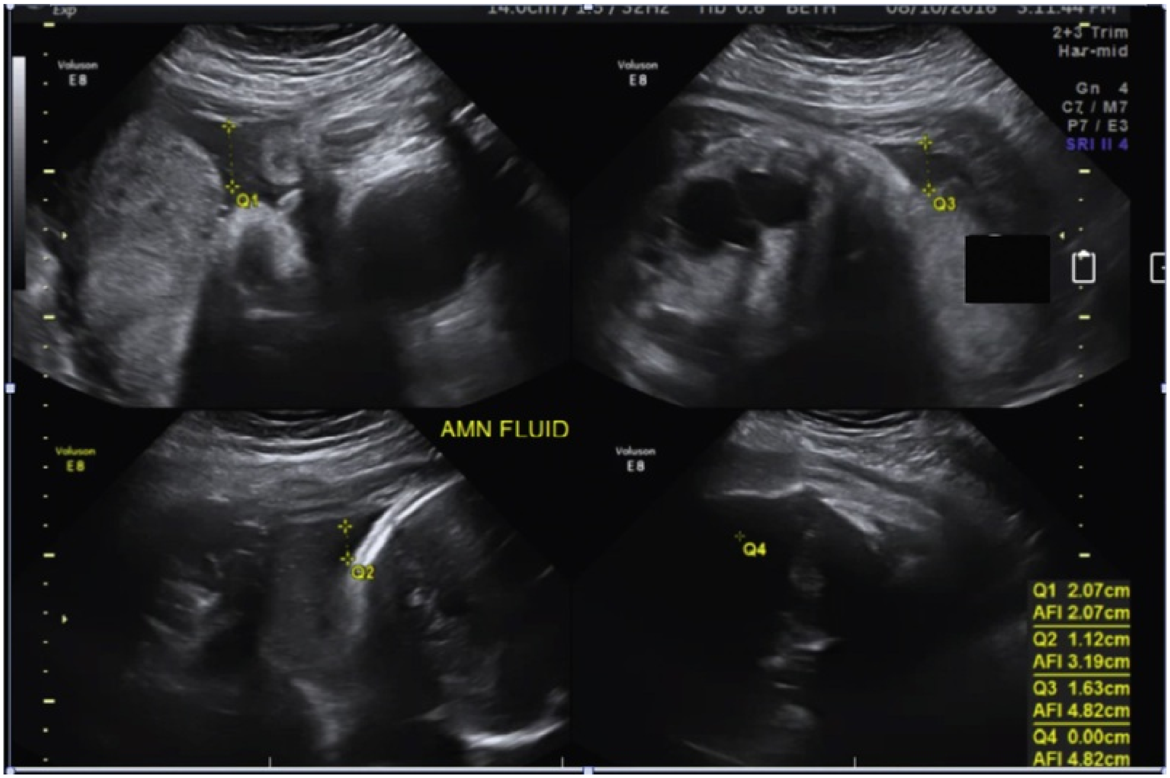

FIG. 22.1 The amniotic fluid index *(AFI)* is calculated by measurement of the four largest pockets of amniotic fluid.

The dilated urinary tract appears to be ideal for detection by ultrasonography, and several large studies have reported sensitivities of up to 89% (Grandjean et al., 1999; Stefos et al., 1999). Equally, over the past decade there has been a steady increase in the number of fetal ultrasound scans performed despite the lack of medical literature to support that prenatal identification of fetal anomalies improves outcome (Hsieh et al., 2009). Furthermore, this increased utilization of prenatal ultrasonography will lead to increased health care costs in the United States, with an estimate for 1 million mothers screened up to $270 million (Vintzileos et al., 2000).

The ability for prenatal ultrasonography to accurately determine the postnatal diagnosis varies. For example, Lee et al. (2006) **demonstrated a linear relationship between increasing severity of prenatal UTD and UPJO that does not exist with other common conditions such as VUR or duplex anomalies.** For rare conditions, a high index of suspicion affords the opportunity to make the correct diagnosis, but this varies as well. Conditions such as bladder/cloacal exstrophy and neural tube defects can be correctly diagnosed in a majority of patients, and diseases that affect genital ambiguity are not as consistently diagnosed (Boyd et al., 2008; Cheikhelard et al., 2000; Julian-

Reynier et al., 1994; Wiesel et al., 2005).

The main benefit of prenatal detection of urologic anomalies is to allow for the opportunity for open dialogue concerning the pathologic finding as it relates to the differential diagnosis, role for prenatal intervention, role of postnatal imaging, and natural history of the suspected disease (Clayton and Brock, 2011, 2018).

Fetal Magnetic Resonance Imaging

The use of fetal magnetic resonance imaging (MRI) is limited for the evaluation of prenatal UTD. The main indication for this modality is the need for specific anatomic detail. Many of these situations are rare, such as cloacal anomaly, urogenital sinus, cloacal/bladder exstrophy, and duplication anomalies that may result in bladder outlet obstruction (BOO) (Fig. 22.2).

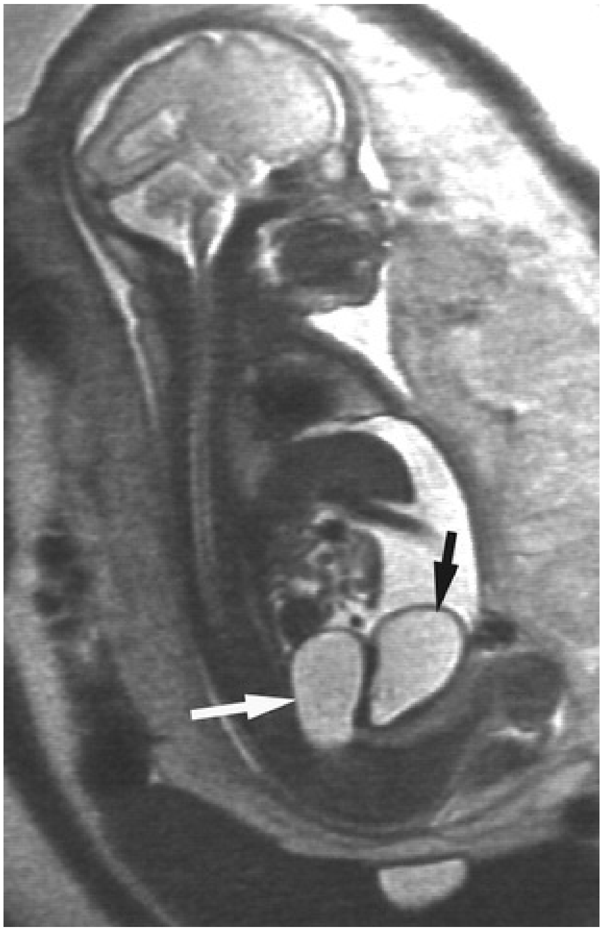

FIG. 22.2 Fetal magnetic resonance image demonstrating cloacal anomaly *(arrows)*.

Fetal MRI offers superiority over ultrasound imaging in regard to specific anatomic detail that may not be obtained with fetal ultrasonography, which has inherent factors such as amniotic fluid volume, maternal body habitus, fetal position, or pelvic bony structures (Hayashi et al., 2005).

Key Points

- The initial screening maternal ultrasound scan is performed around 20 weeks' gestation. Low-risk pregnancies average two scans, and high-risk pregnancies average four scans throughout pregnancy.
- Urinary tract dilation represents the second most common condition detected prenatally and occurs in 1% to 3% of pregnancies.
- Ultrasonography cannot reliably predict the severity of disease for all urologic conditions. It tends to correlate best with obstructive lesions such as UPJO or posterior urethral valve (PUV) and less with VUR.
- Prenatal detection of urologic disease affords the opportunity for the family to meet with a specialist before delivery to become informed about the anticipated course and natural history of the suspected diagnosis.

Grading Systems

Although a common condition, there is a lack of consensus in regard to the most useful grading system for the description of perinatal UTD. Zanetta et al. identified this discrepancy in a multispecialty survey that queried obstetricians, pediatricians, pediatric urologists, and pediatric radiologists. The authors demonstrated that a majority of providers use the anterior-posterior diameter (APD) system prenatally in comparison to postnatally, when the Society for Fetal Urology (SFU) or subjective (mild, moderate, severe) systems were more commonly employed (Zanetta et al., 2012).

Classification systems used to grade perinatal UTD rely on either objective or subjective findings and with some, a combination of the two. The three most common systems used that will be discussed include the anterior-posterior renal pelvic diameter (APRPD), SFU, and Urinary Tract Dilation (UTD) classification systems.

Anterior-Posterior Renal Pelvic Diameter

The most common system used prenatally by maternal-fetal specialists is the anterior-posterior renal pelvic diameter/anterior-posterior diameter (APRPD/APD) system. This strictly objective system is simple and defines the measurement by obtaining the diameter while measuring the kidney in the transverse plane at the mid-level of the kidney. The renal hilum can be used as an indicator of the optimal location of this measurement. The main drawback to this system is that it is operator dependent, which may lead to inaccurate measurements. For example, a common error occurs when the measurement of APD is taken with the kidney in the sagittal as opposed to the transverse plane.

Normative values are described for APD indexed with gestational age. An APD of less than 4 mm before 28 weeks and less than 7 mm after 28 weeks are considered physiologic. **A three-tier subjective grading system has been described that inversely correlates the incidence with the severity of urinary tract dilation** (Table 22.1). Several centers have demonstrated positive correlation between gestational age and APD. The physiologic increase in urine production that occurs in the third trimester may be a factor that accounts for this correlation (Chitty and Altman, 2003; Odibo et al., 2003).

TABLE 22.1

Fetal Urine Biochemistry Profile

Sodium	<100 mg/dL
Calcium	<8 mg/dL
Osmolarity	<200 mOsM/L
Total protein	<20 mg/dL
β_2-Microglobulin	<4 mg/L

From Johnson MP, Bukowski TP, Reitleman C, et al. In utero surgical treatment of fetal obstructive uropathy: a new comprehensive approach to identify appropriate candidates for vesicoamniotic shunt therapy. *Am J Obstet Gynecol* 170(6):1772 (Table 1), 1994.

Lee et al. (2006) **demonstrated that the severity of prenatal dilation demonstrates a linear relationship with obstructive lesions such as UPJO and posterior urethral valve (PUV) while demonstrating an inconsistent relationship with VUR** (Table 22.2).

TABLE 22.2

Definition of Antenatal Hydronephrosis by Anteroposterior Diameter and Estimated Severity Percentage Range

DEGREE	ANTEROPOSTERIOR DIAMETER		SEVERITY
	SECOND TRIMESTER	THIRD TRIMESTER	
Mild	4 to <7 mm	4 to <9 mm	56.7%–88.0%
Moderate	7 to ≤10 mm	9 to ≤15 mm	10.2%–29.8%
Severe	>10 mm	>15 mm	1.5%–13.4%

Data from Feldman et al., 2001; Ahmad and Green, 2005; Wollenberg et al., 2005; Lee RS, Cendron M, Kinnamon DD, Nguyen HT. Antenatal hydronephrosis as a predictor of postnatal outcome: a meta-analysis. *Pediatrics* 118(2):586–593, 2006; Coelho GM, Bouzada MCF, Pereira AK, et al. Outcome of isolated antenatal hydronephrosis: a prospective cohort study. *Pediatr Nephrol* 22(10):1727–1734, 2007. Coelho et al, 2008.

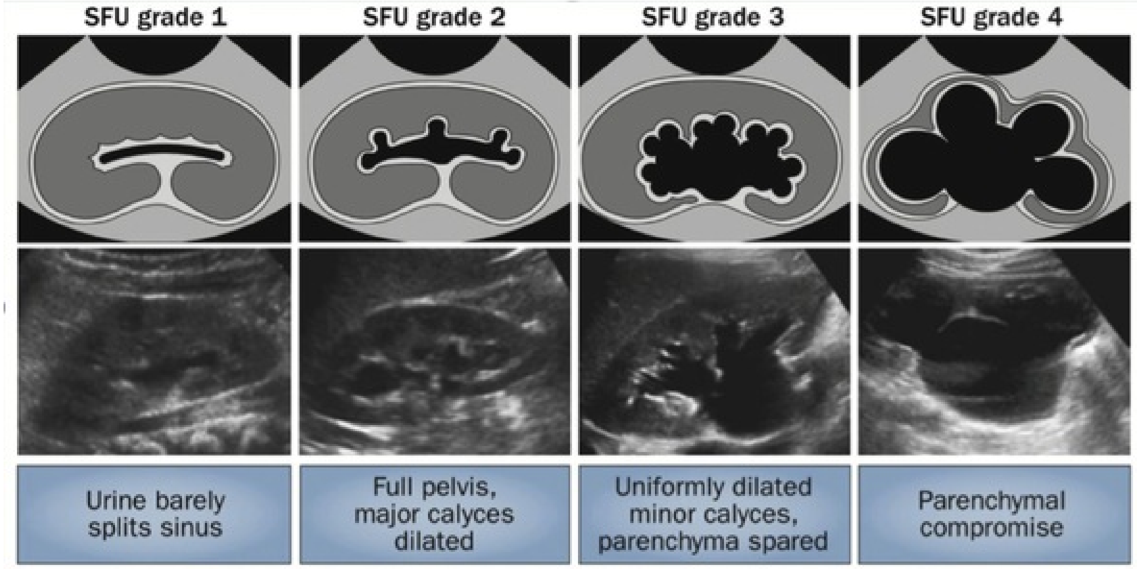
Several centers have demonstrated an APD threshold that may be predictive of the need for urologic surgery, most of which is repair of UPJO (Burgu et al., 2012; Coplen et al., 2006; Dhillon, 1998; Shamshirsaz et al., 2012).

The initial report performed at Great Ormond Street involved a randomized surgical intervention trial for patients with third-trimester prenatal APD greater than or equal to 15 mm and greater than 40% differential renal function. A total of 75 patients were prospectively randomized to surgical intervention of observation. In the surgery arm, 38 of 39 patients maintained renal function and demonstrated a decrease in dilation. For the observation arm, 17 of 36 patients improved, 12 remained stable, and 7 required intervention because of decreased function, and the APD ranged from 20 to 40 mm (Dhillon, 1998). Unfortunately, longitudinal data are lacking in this cohort, and thus the only conclusions represent short-term observations.

In general, it is difficult to set an exact limit on an APD threshold. Setting a low APD cutoff will increase the sensitivity of detection of UPJ but may result in significant overtesting. Likewise, raising the cutoff will result in increased specificity but will carry the risk for underdiagnosing urologic disease.

Society for Fetal Urology Grading System

The SFU is a subjective 5-point grading system that relies on a combination of renal pelvis/calyceal dilation and the integrity of the renal parenchyma (Fernbach et al., 1993) (Fig. 22.3). The system is simple but does demonstrate variability with intrarater and interrater variability with certain grades, which is to be expected with a completely subjective system (Vemulakonda et al., 2015). Interestingly, computer-enhanced visual learning appears to be an effective means of teaching the grading system to health care providers (Liu et al., 2015; Marks et al., 2011). The Chicago group demonstrated effectively through pretesting and post-testing that interactive computer module learning improved reliability of grading kidney dilation with the SFU system (Liu et al., 2015; Marks et al., 2011).



SFU grade 1
SFU grade 2
SFU grade 3
SFU grade 4
Urine barely splits sinus
Full pelvis, major calyces dilated
Uniformly dilated minor calyces, parenchyma spared
Parenchymal compromise

FIG. 22.3 Figures and ultrasound images demonstrating the Society for Fetal Urology (SFU) grading system. (Modified from Timberlake MD, Herndon CD. Mild to moderate postnatal hydronephrosis—grading systems and management. *Nat Rev Urol* 10[11]:652 [Figure 2], 2013).

The SFU system has been demonstrated to be predictive of both renal function and the need for surgical intervention in patients with prenatal urinary tract dilation. In 2007, Erickson et al. reported an inverse correlation between SFU grade and preserved differential renal function (>40%). A total of 33 of 33 (100%) patients with SFU grade 3 demonstrated retained function in comparison to only 27 of 38 (71%) with SFU grade 4 (Erickson et al., 2007). Some have used this as a basis for limiting the use of renal scintigraphy for the evaluation of postnatal urinary tract dilation (Herndon, 2012). In a retrospective review of 125 patients with prenatal UTD, Ross et al. found the SFU system to be predictive of the timing and need for surgical intervention. Three groups consisting of early surgical intervention, delayed surgical intervention, and continued observation were analyzed with respect to distribution of SFU grade. For early surgical intervention, most (89%) patients demonstrated SFU grade 4. For continued observation, most (78%) patients demonstrated SFU grade 3. For those that had delayed surgical intervention, SFU grade correlated less, with 62% demonstrating SFU grade 4 (Ross et al., 2011).

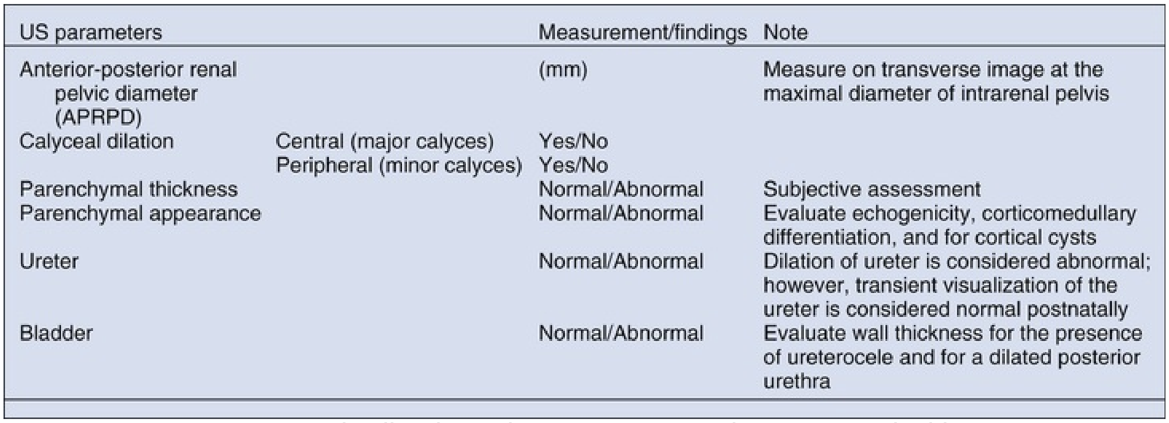
The SFU system is a simple system that can be easily learned and demonstrates the ability to predict renal function and the need for surgical intervention (Erickson et al., 2007; Kilby and Morris 2014; Liu et al., 2015; Marks et al., 2011; Ross et al., 2011). However, the subjective nature does limit its applicability, and other specialties do not appear to be using this system. Furthermore, it does not take into account the entire collecting system including the urinary bladder and ureter, which may affect postnatal decision making and are incorporated into other grading systems (Nguyen et al., 2014).

Urinary Tract Dilation Grading System

To address the lack of uniformity, the UTD grading system was developed by a multidisciplinary team that published a Consensus Statement in 2014. To address the lack of consistency in nomenclature, the group elected to use the term *urinary tract dilation (UTD).* Terms such as *hydronephrosis, caliectasis, pelviectasis,* and *pelvicaliectasis* were discouraged.

Great effort was made to develop a standardized technique for ultrasound imaging and principles for data reporting. The group felt that developing a standard process for the technique used for ultrasound imaging was crucial. Prenatally, it was felt that the measurement of the APD should be obtained with the spine of the fetus in the 6 o'clock or 12 o'clock position.

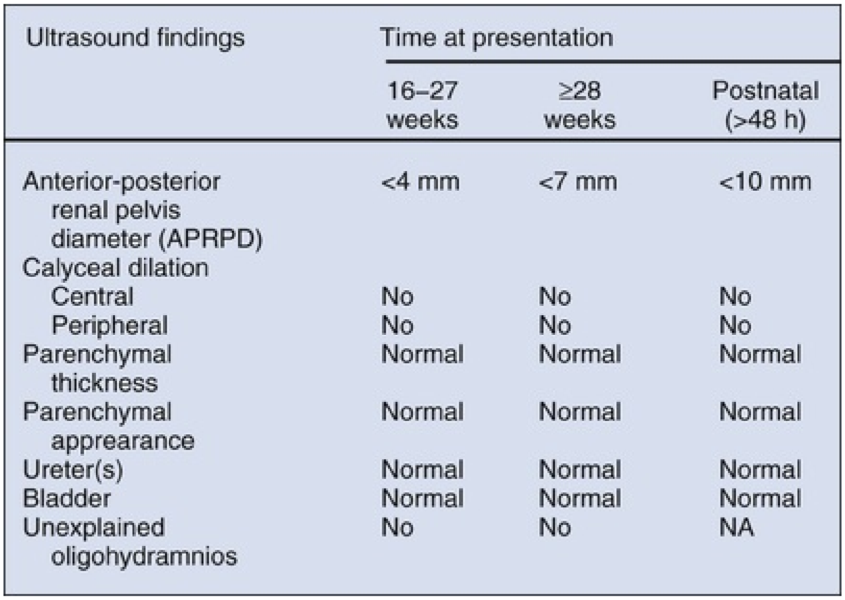
Postnatally, the APD should be obtained at the midpoint of the kidney in the transverse plane, which corresponds to the area of the hilar vessels. The maximal diameter of the renal pelvis should be obtained within the confines of the renal cortex. Finally, comparative studies should be in the same orientation of lie for the baby (supine versus prone). **The grading system consists of a 6-point template that combines two of the most common systems employed (APD and SFU) and includes both objective and subjective evaluation** (Fig. 22.4). The purpose of a standardized reporting template is to allow for a consistent evaluation that transcends the prenatal and postnatal periods (Nguyen et al., 2014).



US parameters		Measurement/findings	Note
Anterior-posterior renal pelvic diameter (APRPD)		(mm)	Measure on transverse image at the maximal diameter of intrarenal pelvis
Calyceal dilation	Central (major calyces)	Yes/No	
	Peripheral (minor calyces)	Yes/No	
Parenchymal thickness		Normal/Abnormal	Subjective assessment
Parenchymal appearance		Normal/Abnormal	Evaluate echogenicity, corticomedullary differentiation, and for cortical cysts
Ureter		Normal/Abnormal	Dilation of ureter is considered abnormal; however, transient visualization of the ureter is considered normal postnatally
Bladder		Normal/Abnormal	Evaluate wall thickness for the presence of ureterocele and for a dilated posterior urethra

FIG. 22.4 Standardized 6-point parameters to be measured with ultrasonography using the urinary tract dilation classification system. (Modified from Nguyen HT, Benson CB, Bromley B, et al. Multidisciplinary consensus on the classification of prenatal and postnatal urinary tract dilation [UTD classification system]. *J Pediatr Urol* 10[6]:998 [Table 2], 2014).

In effort to mitigate postnatal overtesting, the UTD working group established a normative value for postnatal APD, which paralleled those observed for the prenatal period. An APD cutoff of less than 10 mm was selected in the absence of calyceal or ureteral dilation and felt to represent nonpathologic renal pelvis dilation. When combined with the accepted normative values for the prenatal period, a stepwise progression of nonpathologic renal pelvic dilation can be seen (Fig. 22.5).



Ultrasound findings	Time at presentation		
	16–27 weeks	≥28 weeks	Postnatal (>48 h)
Anterior-posterior renal pelvis diameter (APRPD)	<4 mm	<7 mm	<10 mm
Calyceal dilation			
Central	No	No	No
Peripheral	No	No	No
Parenchymal thickness	Normal	Normal	Normal
Parenchymal apprearance	Normal	Normal	Normal
Ureter(s)	Normal	Normal	Normal
Bladder	Normal	Normal	Normal
Unexplained oligohydramnios	No	No	NA

FIG. 22.5 Normative thresholds for prenatal and postnatal anterior-

posterior diameter. (Modified from Nguyen HT, Benson CB, Bromley B, et al. Multidisciplinary consensus on the classification of prenatal and postnatal urinary tract dilation [UTD classification system]. *J Pediatr Urol* 10[6]:989 [Table 3], 2014.)

The intent of this reclassification was to create a more pragmatic approach to the postnatal evaluation of UTD. Parents should be advised that prenatal UTD represents a spectrum of disease, and significant pathologic conditions such as VUR may exist in the absence of pathologic renal pelvis dilation (Herndon et al., 1999b). Nonetheless, a paradigm shift has occurred in regard to the recommendation of invasive testing such as a voiding cystourethrogram (VCUG) that is no longer based solely on the probability of diagnosing VUR. A comprehensive risk stratification that includes urinary tract infection (UTI) should drive this recommendation, which is discussed later in this chapter (Zee et al., 2016).

Key Points

- An inverse relationship exists between the severity of UTD and the incidence of urologic disease.
- APD demonstrates a linear relationship for obstructive lesions such as UPJO and PUV.
- An APD of 15 in the third trimester demonstrates reasonable positive predictive value for the need for surgery for UPJO.
- The SFU system consists of a 5-point grading system that is based on calyceal dilation and integrity of the parenchyma.
- The UTD system consists of a combination of APD and SFU systems with the additional inclusion of the lower urinary tract and employs a standardized reporting system and risk stratification.

Prenatal Multidisciplinary Consultations

One of the main benefits of prenatal detection of urologic anomalies is the opportunity for discussion with the family and physician. Certain urologic conditions that may require immediate or urgent intervention postnatally are best served by multidisciplinary prenatal consultation. All stakeholders involved in the care of the mother and child should ideally develop a plan of care with agreed-upon responsibilities. These conditions include cloacal/bladder exstrophy, cloacal/urogenital sinus malformation, autosomal recessive polycystic kidney disease, BOO (PUV, prune belly syndrome, or urethral atresia), and myelomeningocele/neural tube defect spectrum of disease.

Parental Counseling for Fetal Intervention

Prenatal counseling for LUTO should include the maternal-fetal obstetrician, pediatric urologist, pediatric nephrologist, and neonatologist. A candid discussion should include a clear picture that captures our current state of understanding of the role of intervention. Although we have some unanswered questions related to those who may benefit, several statements can be reliably conveyed to the family. **First, fetal intervention will improve perinatal survival when indicated but carries significant risk with a collective reported complication rate to the mother and fetus of over 40%** (Elder et al., 1987; Morris et al., 2013)**. Second, selective treatment that affords perinatal survival has not been demonstrated to provide a reliable long-term impact on the need for renal replacement. This burden may be significant and lifelong. Third, every patient should be individualized in regard to a risk/benefit analysis that must allow for shared decision making in a multidisciplinary setting.**

Parental Counseling for Prenatal Surgery for Myelomingocele Closure

A multidisciplinary consultation should include the maternal/fetal obstetrician, pediatric neurosurgeon, pediatric urologist, and neonatologist. A complete fetal survey including echocardiogram should be completed along with a karyotype to aid in discussion with the family. Parents should be aware of the experimental nature of fetal myelomeningocele closure, and the procedure should only be performed at specialized centers that can be found at the North American Fetal Therapy Network (NAFTNet) website (https://www.naftnet.org/). Although it appears to have a positive role for decreasing the need for ventriculoperitoneal (VP) shunting and improving cognitive/motor function, the impact on overall bladder function does not appear to be meaningful (Adzick et al., 2011; Clayton et al., 2011; Danzer et al., 2009, 2016; Diwakar et al., 2013; Tulipan et al., 2015). Because of its experimental nature, the American College of Obstetricians and Gynecologists and the Society for Maternal-Fetal Medicine made recent recommendations that include the following:

> - Open maternal-fetal surgery for myelomeningocele repair has been demonstrated to improve a number of important pediatric outcomes at the expense of procedure-associated maternal and fetal risks.
> - Women with pregnancies complicated by fetal myelomeningocele who meet established criteria for in utero repair should be counseled in nondirective fashion regarding all management options, including the possibility of open maternal-fetal surgery.
> - Interested candidates for fetal myelomeningocele repair should be referred for further assessment and consultation to a fetal therapy center that offers this intervention and possesses the expertise, multidisciplinary team, services, and facilities to provide detailed information regarding maternal-fetal surgery and the intensive care required for patients who choose to undergo open maternal-fetal surgery (Committee on Obstetric Practice, Society for Maternal-Fetal Medicine, 2017).

Key Points

- Prenatal intervention for LUTO appears to improve perinatal survival but does not reliably affect long-term renal function.
- Parental consultation for fetal myelomeningocele closure should take place

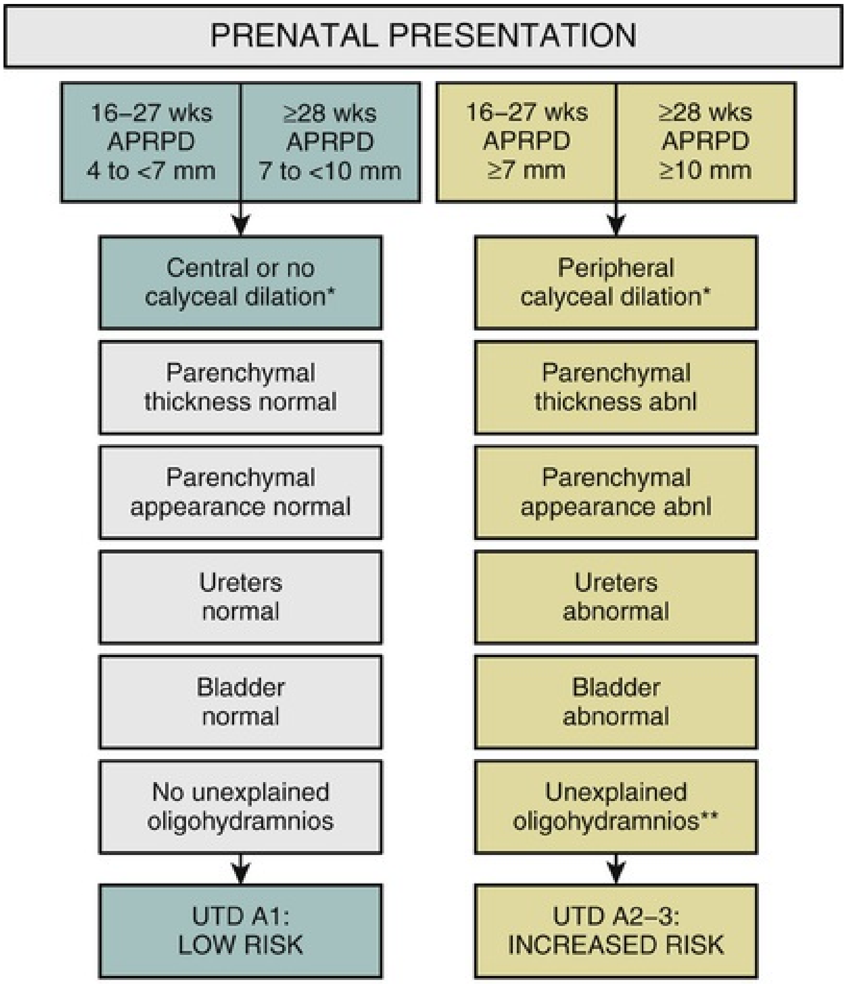
at a center with expertise in fetal surgery that offers a multidisciplinary approach.

- Fetal surgery for myelomeningocele appears to improve motor/cognitive skills and decrease the need for VP shunting but offers no definitive benefit to bladder function.

Urinary Tract Dilation

Risk Stratification and Management for Prenatal Urinary Tract Dilation

The 6-point evaluation described with the UTD system is used to assign two levels of risk prenatally (A1 is low risk, and A2/A3 is increased risk). The allowable APD threshold transitions at 27 weeks' gestational age to allow for an increase in fetal growth and the physiologic urine production that occurs in the third trimester. **A1 (low risk) was defined as 4 to 7 mm APD or 7 to 10 mm APD from 16 to 27 weeks and after 28 weeks, respectively. Aside from central calyceal dilation (or dilation of the major calyx/infundibula), all other parameters measured were normal. A2/A3 (increased risk) was defined as APD greater than 7 mm at 16 to 27 weeks or greater than 10 mm after 28 weeks, respectively, and/or positive values for one of the other five parameters** (Fig. 22.6). Recommendations based on the risk assessment dictate subsequent follow-up within the prenatal period.



PRENATAL PRESENTATION
16–27 wks APRPD 4 to <7 mm
≥28 wks APRPD 7 to <10 mm
16–27 wks APRPD ≥7 mm
≥28 wks APRPD ≥10 mm

Multidisciplinary consensus on the classification of prenatal and postnatal urinary tract dilation [UTD classification system]. *J Pediatr Urol* 10(6):990 [Figure 3], 2014.)

For A1 UTD detected before 28 weeks, a second ultrasound should be performed after 32 weeks' gestation. For A2/A3, the recommendation was to obtain an ultrasound every 4 months until delivery. The rationale was twofold. First, the anatomic defect may progress significantly, which may alter the plan and location for delivery. Second, the likelihood of detecting a second fetal anomaly was increased with this degree of UDT. An ultrasound scan after 48 hours of birth is recommended in both cohorts. (Fig. 22.7) (Nguyen et al., 2014).

Prenatal Management

Prenatal Intervention for Lower Urinary Tract Obstruction

The male fetus that presents with severe bilateral urinary tract dilation that includes the bladder, ureters, and kidneys with decreased amniotic fluid should be felt to have LUTO. This condition is a spectrum of disease, and thus each case, when identified, should be individualized as should the discussion with the families (Moslehi et al., 2001). The discussion with the family should be framed around the potential benefit of fetal intervention compared with implicit risks to both the fetus and the mother.

The constituents of amniotic fluid shift from the placenta to fetal urine during the 16th week of gestation (Pathak and Lees, 2009). Ideally, restoration of amniotic fluid will facilitate pulmonary development and potentially facilitate renal development as well. Mandell et al. determined through an observational cohort study that oligohydramnios that presents after 27 weeks appeared to lend a favorable outcome regarding pulmonary development (Mandell et al., 1992). Thus fetal intervention should be reserved for those that develop this condition very early in the second trimester. The overall need for intervention is rare and estimated to be about 1 : 60,000 (Herndon et al., 2000). **Several large systematic reviews have concluded that although feasible, there does not**

appear to be sufficient evidence to endorse its use to reliably affect long-term renal function. However, it is clear that postnatal survival is improved in part because those that do not have amniotic fluid restored will suffer fetal and/or neonatal demise (Biard et al., 2005; Clayton and Brock 2012, 2018; Coplen, 1997; Crombleholme et al., 1990; Freedman et al., 1999; McLorie et al., 2001; Morris et al., 2010; Nassr et al., 2017; Smith-Harrison et al., 2015).

Fetal intervention consists of early delivery, fetal shunting, or fetal surgery (Biard et al., 2005; Clayton and Brock 2012, 2018; Coplen 1997; Crombleholme et al., 1990; Freedman et al., 1999; Morris et al., 2010, 2011; Smith-Harrison et al., 2015). Interestingly, practice pattern variation exists between non-ultrasound and ultrasound physicians who would recommend early delivery in situations of early third-trimester identification of BOO, confirmed lung maturity and decreasing amniotic fluid (Herndon et al., 2000). When invasive fetal intervention is considered in the form of vesicoamniotic shunt (VAS) placement or fetal cystoscopy, a serial assessment of fetal urine should be performed to serve as a basis for renal function.

Fetal intervention carries significant risk to the pregnancy, and thus all procedures are performed in the controlled environment of the operating room with epidural anesthesia. The fetal anesthesia consists of injection of narcotics and/or paralytics into the umbilical vein with the aid of ultrasonography. Percutaneous assess is obtained with both VAS placement or fetal cystoscopy. **The clear advantage of fetal cystoscopy is the ability to directly visualize the posterior urethra and establish the diagnosis allowing for directed intervention.**

Fetal urine biochemistry that should be assessed includes urinary sodium, calcium, osmolarity, total protein, and β_2-microglobulin (Table 22.3). Serial bladder aspirations have proven more effective at determining renal function. In 1995, a total of 29 fetuses were managed with a minimum of three aspirations and demonstrated that the final urine collection was the strongest correlate with poor renal function (Johnson et al., 1995). In 2007, a systematic review of 23 studies revealed that urinary calcium and sodium were the strongest predictors of poor renal function, and β_2-microglobulin was less predictive (Morris et al., 2007). However, in 2015, a retrospective review of 72 cases in which fetal urine was obtained before 23 weeks revealed that sodium and β_2-microglobulin were significant predictors along with calcium (Abdennadher et al., 2015). Clinical predictors of poor renal function include oligohydramnios, renal parenchymal cysts, or increased echogenicity (Morris et al., 2007). However, fetal ultrasound urinary tract findings do not correlate with fetal urine biomarkers in their ability to predict renal function.

[a] Pointwise 95% confidence intervals were estimated by logistic regression with robust standard errors based on generalized estimating equations with a working independence correlation structure to adjust for clustering by study for all degrees of antenatal hydronephrosis except mild-moderate. Because only one study had subjects with mild-moderate antenatal hydronephrosis, the pointwise 95% CIs had to be estimated using logistic regression with unadjusted standard errors.

[b] Testing for trend in risks with increasing degree of antenatal hydronephrosis using logistic regression with robust standard errors based on generalized estimating equations with a working independence correlation structure.

[c] Includes prune-belly syndrome, VATER (vertebral, anal, tracheo-esophageal and renal anomalies) syndrome, solitary kidney, renal mass, and unclassified causes.

CI, Confidence interval.

Modified from Lee RS, Cendron M, Kinnamon DD, Nguyen HT. Antenatal hydronephrosis as a predictor of postnatal outcome: a meta-analysis. *Pediatrics* 118(2):590, 2006.

In 1982, the initial clinical experience was described for fetal intervention for BOO. Two patients had obstruction relieved in utero with fetal surgery, and both died in the early neonatal period as a result of renal failure. Seven patients were found to have equivocal renal function, and three underwent percutaneous shunt placement. Two survived and were felt to do well (Harrison et al., 1982).

With this early success, specialized centers began to pursue this endeavor in the early 1980s. One of the practical challenges was re-creating amniotic space to allow for placement of the shunt, which was alleviated with amnioinfusion (Pathak and Lees, 2009). With rapid expansion of this procedure, a number of complications began to surface, which challenged physicians to re-evaluate the benefit of intervention. Elder described a 44% complication rate for the first 57 reported patients who received fetal intervention. Specific complications included incomplete drainage (19%), premature labor (12%), urinary ascites (7%), and chorioamnionitis (5%) (Elder et al., 1987). Various case reports such as bowel herniation and direct injury to the fetus have equally been reported (Robichaux et al., 1991) (Fig. 22.8). The most common technique employed is percutaneous placement, and current models of shunt, such as the Rodeck, are designed to mitigate migration by lying flush against the abdominal wall in contrast with the original Harrison shunt (Farrugia 2016; Johnson et al., 1994) (Fig. 22.9).

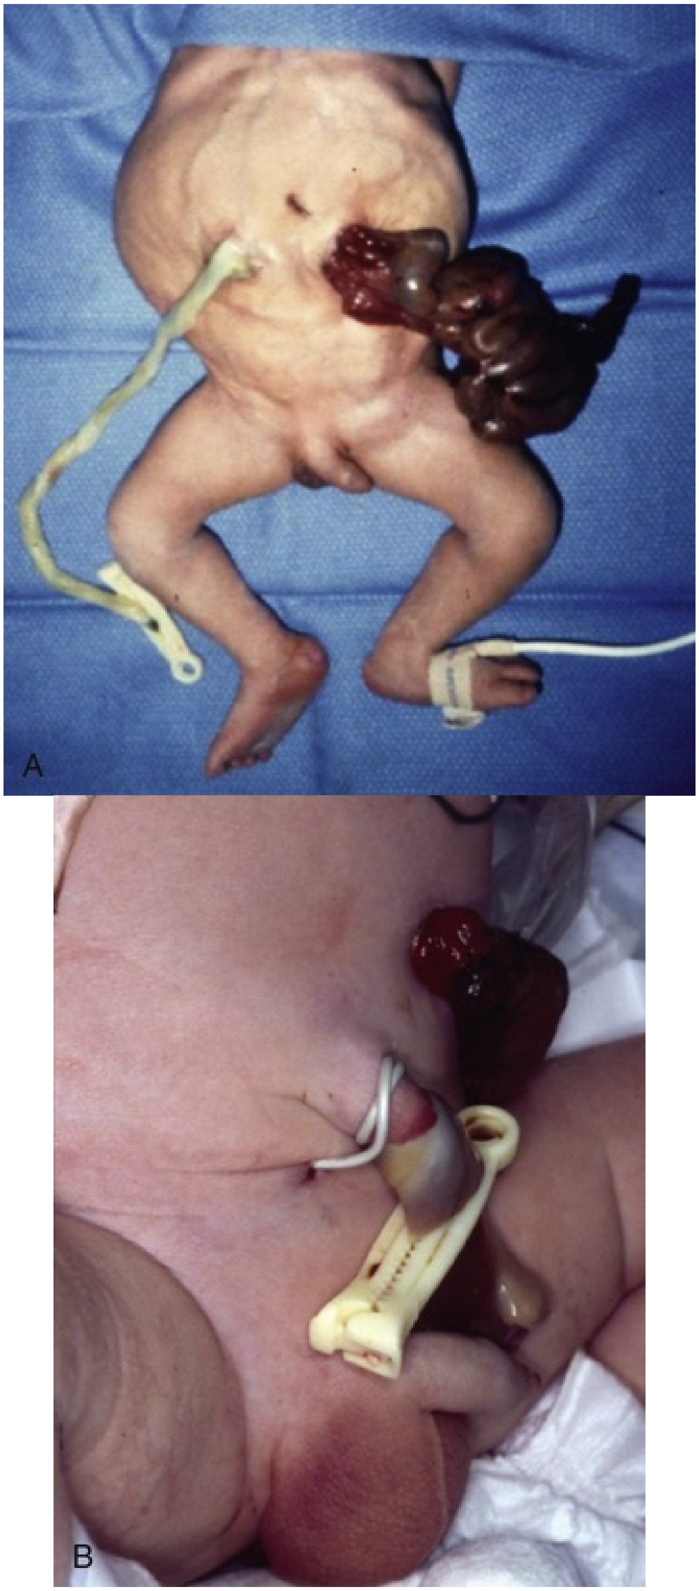

FIG. 22.8 Photo of neonates with previous insertion of vesicoamniotic shunt with herniation of bowel (A) and strangulation of umbilicus (B).

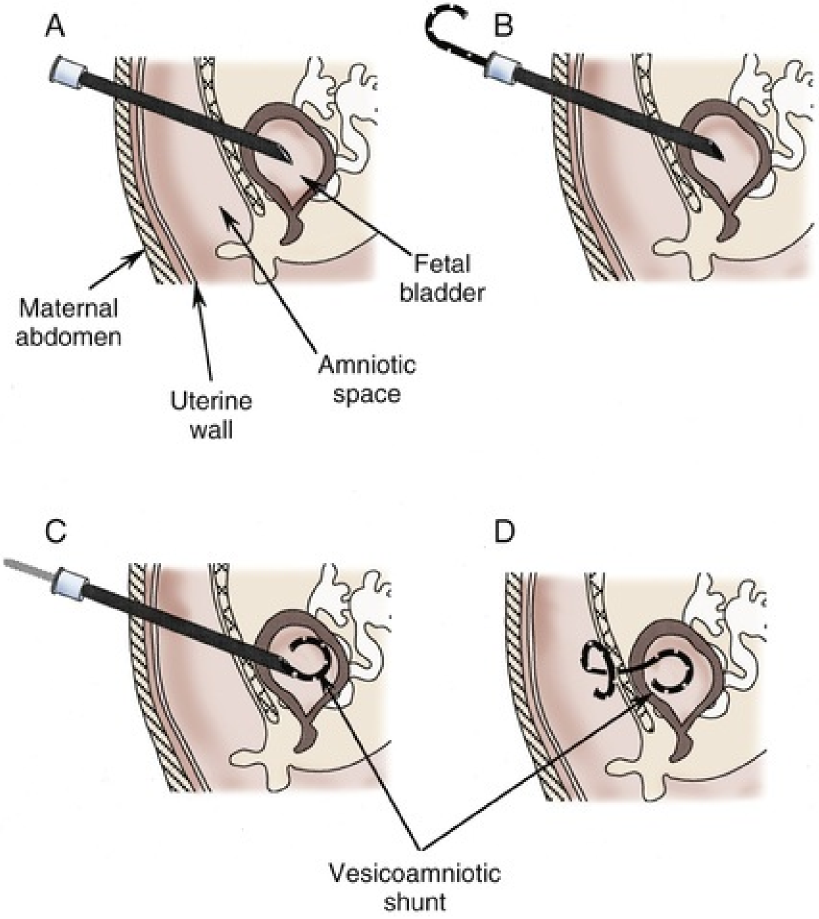

FIG. 22.9 Diagram showing technique of fetal vesicoamniotic shunt placement. The fetal bladder is initially reached with a needle, and a large-bore introducing sheath is passed into the bladder (A). Within this sheath, the shunt is passed (B and C). It is a double-pigtail shunt with holes at each end allowing free drainage between the bladder and amniotic space (D). (From Peters CA. Surgical management of fetal uropathies. In: Marshall FF, ed. *Textbook of operative urology.* Philadelphia, PA: Saunders; 1996:1063.)

The Philadelphia group reported long-term clinical outcome following VAS placement in 20 patients with a mean follow up of 5.8 years. The protocol included fetal ultrasound findings consistent with BOO from 18 to 22 weeks' gestational age with an assessment of renal function with three separate aspirations of the fetal bladder. Fetal urine profile was a predictor of early neonatal survival with 13 good, 2 borderline, and 3 poor. The diagnoses varied with PUV in 7, urethral atresia in 4, and prune belly syndrome in 7. Renal insufficiency was present in 10 of 18 patients, with 6 requiring renal replacement therapy. Bladder symptoms were felt to be adequate, with 6 patients requiring CIC. Of note, formal urodynamic studies were not reported, although 10 patients spontaneously voided with 1 other patient diverted with vesicostomy. Interestingly, quality of life was similar to the normal population and greater than other patients with chronic disease (Biard et al., 2005).

The Percutaneous Shunting in Lower Urinary Tract Obstruction (PLUTO) trial was a multicenter prospective randomized trial designed to assess the efficacy of fetal intervention. The eligible population included those with evidence of BOO in which the benefit of intervention was unclear. The study was prematurely terminated because of poor enrollment. A total of 31 patients were randomized, with 16 undergoing successful VAS placement and 15 observed. Perinatal death as expected was higher in the observed cohort (33% versus 66%). Equally, no meaningful impact on renal function was demonstrated, although two patients demonstrated normal renal function. Complications occurred in 7 of 16 (44%), with 3 premature rupture of membranes and 4 nonfunctional shunts (Morris et al., 2013a) (Fig. 22.10).

FIG. 22.10 Outcomes of 31 patients enrolled in the Percutaneous Shunting in Lower Urinary Tract Obstruction (PLUTO) trial. (Modified from Morris RK, Malin GL, Quinlan-Jones E, et al., for the Percutaneous vesicoamniotic shunting in Lower Urinary Tract Obstruction [PLUTO] Collaborative Group. Percutaneous vesicoamniotic shunting versus conservative management for fetal lower urinary tract obstruction [PLUTO]: a randomised trial. *Lancet* 382[9903]:1497 [Figure 1], 2013a.)

Fetal Cystoscopy

In theory, fetal cystoscopy offers several distinct advantages over VAS placement with the similar benefit of decompression of the obstructed urinary system with return of amniotic fluid to promote pulmonary development and the potential to improve renal function. Direct visualization of the cause for LUTO has improved the ability to obtain a fetal diagnosis and affords the opportunity for directed intervention that will allow bladder cycling without the dependence on a functional device throughout pregnancy (Morris et al., 2011; Quintero et al., 2000; Ruano et al., 2010, 2015; Sananes et al., 2016). Associated complications are similar to VAS placement with the addition of urethrocutaneous and rectourethral fistula formation, which has been reported in up to 10% (Sananes et al., 2016). This in part is caused by the anatomic disadvantage associated with antegrade access and use of LASER energy to ablate the valve.

The first report of fetal cystoscopic ablation (FCA) of PUV was presented by Quintero's team as a case report at the Society for Fetal Urology annual meeting in 1999. Suprapubic access allowed the use of a neodymium-doped yttrium aluminum garnet (Nd:Yag) LASER to ablate the valve in an antegrade manner. After this successful attempt, several specialized centers employed this technique, and the results of published series have been mixed. In 2011, a systematic review of the literature identified four studies including 63 patients and revealed that fetal cystoscopy demonstrated a significant perinatal survival advantage over observation but was equivocal when compared with VAS placement (Morris et al., 2011). In 2016, short-term outcomes for 50 fetal cystoscopies revealed accuracy of diagnosis of LUTO in 91% of patients with 62% having PUV, 28% urethral atresia, and 10% urethral stenosis. Success was best achieved in the PUV group with 17 of 30 (57%) surviving and 13 of 17 (78%) having normal renal function at 1 year and 15 of 28 (54%) surviving and 11 of 15 (73%) having normal renal function at 2 years (Sananes et al., 2016).

Vesicoamniotic Shunt Placement Versus Fetal Cystoscopy

To assess the efficacy of VAS placement and fetal cystoscopy, a multicenter retrospective review of 111 consecutive patients with LUTO was performed. The strict inclusion criteria included were: diagnosis between 16 and 26 weeks, severe LUTO on fetal ultrasonography, absence of other anatomic abnormalities including cardiac echocardiogram, favorable urine electrolytes, and normal male karyotype. A total of 50 patients underwent fetal intervention (34 cystoscopy with laser ablation, 16 VAS) compared with 61 patients treated expectantly. The study did include previously published case studies.

Both VAS placement and FCA demonstrated a clear survival advantage when compared with observation alone for all cases of LUTO, with an adjusted relative risk (ARR) of 1.86 (95% confidence interval [CI], 1.01 to 3.42; P = 0.048) and 1.73 (95% CI, 1.01 to 3.08; P = 0.04), respectively. **Interestingly, for those diagnosed postnatally with PUV, FCA demonstrated an improvement in both 6-month survival (ARR 4.10; 95% CI, 1.75 to 9.62; $P < 0.01$) and renal function (ARR 2.66; 95% CI, 1.25 to 5.70; $P = 0.01$), and VAS only demonstrated an improvement in 6-month survival (ARR 3.76; 95% CI, 1.42 to 9.97; $P < 0.01$) and had no effect on renal function** (Ruano et al., 2015).

Recently, a report from the SFU endorsed a severity of disease classification system developed by Ruano that was indexed to perinatal and renal outcome (Ruano et al., 2016). The purpose was an attempt to better identify patients that may benefit from fetal intervention. Specifically, a combination of subjective and objective fetal parameters that include amniotic fluid volume, echogenicity of fetal kidney, renal cortical cysts, renal dysplasia, favorable urinary biomarkers, and presence of fetal intervention were use to stage patients (Fig. 22.11). **The rate of fetal intervention (either fetal cystoscopy or VAS), death within 24 hours, overall mortality, and need for renal replacement all were more prevalent in Stage III (worse) patients** (Braga et al., 2014).

	Stage I (mild LUTO)	Stage II (severe LUTO, with prenatal findings suggestive of preserved fetal renal function)	Stage III (severe LUTO, with prenatal findings suggestive of fetal abnormal renal function)
Amount of amniotic fluid	Normal	Oligohydramnios or anhydramnios	Oligohydramnios, but usually anhydramnios
Echogenicity of fetal kidneys	Normal	Hyperechogenic	Hyperechogenic
Renal cortical cysts	Absent	Absent	Can be present
Renal dysplasia	Absent	Absent	Can be present
Fetal urinary biochemistry	Favorable	Favorable within three consecutive evaluations	Not favorable after three consecutive evaluations
Fetal intervention	Not indicated	Indicated to prevent pulmonary hypoplasia and severe renal impairment	May be indicated to prevent pulmonary hypoplasia but not postnatal renal impairment; further studies are necessary

The disease can progress from Stage I to Stage II and then to Stage III during pregnancy.
LUTO, Lower urinary tract obstruction.

FIG. 22.11 Classification system proposed by Ruano for prenatal lower urinary tract obstruction. (Modified from Farrugia MK, Braun MC, Peters CA, et al. Report on The Society for Fetal Urology panel discussion on the selection criteria and intervention for fetal bladder outlet obstruction. *J Pediatr Urol* 13[4]:345–351, 2017.)

Key Points

- Clinical predictors of poor outcome are oligohydramnios before 27 weeks, renal cortical cysts, and increased echogenicity.
- Prenatal intervention for LUTO appears to improve perinatal survival but does not reliably affect long-term renal function.
- Fetal cystoscopy affords the opportunity to establish a diagnosis and provide treatment for LUTO.
- Fetal cystoscopy may offer a short-term advantage for overall renal function when compared with VAS placement, but long-term renal data do not exist.

Postnatal Evaluation and Management

Over the past decade, the evaluation and management recommendations for postnatal UTD have become more evidence based (Braga et al., 2015, 2018; Capolicchio et al., 2018; Zee et al., 2016, 2017). A paradigm shift has occurred with recommendations for postnatal imaging and use of PA tailored to a risk assessment, which includes the likelihood of developing a UTI, renal deterioration, or need for surgical intervention. Previously, the evaluation was based on the probability of detecting diseases such as VUR, which occur in up to 24% of patients (Herndon et al., 1999a, 1999b; McLorie et al., 2001).

Imaging

Renal Ultrasound/Resolution of Urinary Tract Dilation

The initial postnatal ultrasound scan, as mentioned earlier, should not be obtained before 48 hours to account for intravascular volume depletion that occurs after delivery. It is important to note that this represents a form of third spacing that is mobilized over the first 24 to 48 hours of life (Maclaurin, 1966). Adherence to the standardization of technique and reporting outlined in the Consensus Statement is recommended (Nguyen et al., 2014). Some have advocated for delaying this initial ultrasound scan for up to 2 weeks postnatally without untoward event. Three levels of risk (P1, P2, and P3) were developed based on the degree of APD and positive values for the remaining five data points: P1 UTD (low risk) includes APD 10 mm to less than 15 mm and central calyceal dilation. P2 UTD (intermediate risk) includes APD greater than or equal to 15 mm and peripheral calyceal or ureteral dilation that may be in isolation. P3 UTD (high risk) includes APD greater than or equal to 15 mm and/or positive values for other data points such as parenchymal cysts or thinning (Fig. 22.12).

Multidisciplinary consensus on the classification of prenatal and postnatal urinary tract dilation [UTD classification system]. *J Pediatr Urol* 10[6]:993 [Figure 6], 2014.)

Resource utilization for the postnatal ultrasound imaging should be indexed to the probability of an untoward event that may affect clinical outcome. A couple of recent prospective studies have assessed the need for continued upper tract monitoring through survival curve analysis and impact of grade on resolution of urinary tract dilation. Zee et al. reported longitudinal follow-up on a multicenter analysis from the SFU registry and demonstrated that 100% of SFU grade 1 and 90% of SFU grade 2 (P1 UTD) will resolve within 30 and 48 months, respectfully (Zee et al., 2017). Similarly, Braga et al. demonstrated similar efficacy for SFU grade and UTD grade to predict resolution of urinary tract dilation that was similar to the outcomes reported with the SFU registry (Braga et al., 2018).

Voiding Cystourethrogram

The use of lower urinary tract imaging for the evaluation of UTD should be evidence based. Similar to using PA, the basis for lower urinary tract imaging has recently changed from the probably of identifying VUR to the risk for developing UTI (Zee et al., 2016). **A systematic review by Lee et al. demonstrated that the degree of upper tract dilation poorly correlates with the grade of VUR, which will be present in up to 31% of patients** (Adra et al., 1995; Lee et al., 2006; Nguyen et al., 2010)**. Furthermore, up to 25% of patients with VUR detected with prenatal UTD will have a normal initial postnatal ultrasound scan** (Herndon et al., 1999b).

Recently, the American Academy of Pediatrics endorsed a standardized approach for performing the VCUG (Frimberger et al., 2016). In general, an attempt should be made to minimize radiation by following the ALARA (as low as reasonably achievable) principal. The policy encourages use of a nonballoon catheter and cycling of the study that should increase reliability of the study. Images that are obtained should include a kidney, ureter, and bladder (KUB) radiograph, bladder filling, and voiding phases.

The recommendation for lower urinary tract imaging should be directed at those most at risk for UTI, which includes females, uncircumcised males, patients with high-grade kidney dilation, and patients with ureteral dilation. The decision is left to the discretion of the urologist after an informed discussion with the family about the risk factors mentioned earlier. Aside from concerns for BOO, which may include a thick-walled bladder (≥0.5 cm), distended urinary bladder, and bilateral hydroureteronephrosis, this study can be obtained as an outpatient. The historical benefit of identifying asymptomatic VUR remains unclear, but several observational studies have demonstrated active surveillance to be a safe and appropriate option for stable patients with known VUR (Kitchens et al., 2010).

Renal Scintigraphy

The role of renal scintigraphy in the evaluation of infants with prenatal UTD varies based on the clinical scenario and question to be answered. Various radionuclides can be used to determine differential renal function, presence of cortical parenchymal defects, and drainage of the collecting system. The main drawback of these studies is the lack of anatomic detail offered with other imaging modalities.

For the evaluation of obstruction in the neonate (or impaired renal function), mercaptoacetyltriglycine (MAG3) is preferred over diethylenetriaminepentaacetic acid (DTPA) because of its superior extraction qualities. Although both have the radionuclide technetium-99m (^{99m}Tc) chelated to them, MAG3 is the agent of choice. For MAG3, the proximal tubule extracts about 50% of the radiotracer with each cycle through the kidney, which then is secreted into the lumen of the collecting system. Additionally, a linear relationship to renal blood flow exists, and this property allows for measurement of renal function.

The standardized “well-tempered” renogram, as described by Conway and Maizels, assures consistency in regard to patient hydration status and bladder decompression, technique utilized in regard to pharmaceutical dose, diuretic dose and timing, and data acquisition and interpretation (Conway and Maizels, 1992). Generally, the patient is exposed to minimal radiation, although a linear relation exists between the degree of obstruction and exposure to radiation (Stratton et al., 2010). **In the asymptomatic infant, findings on MAG3 imaging that may represent a consideration for surgical intervention may include decreased differential function (<40%), T½ greater than 20 minutes, and significant retention on delayed upright imaging** (Sussman et al., 2017) (Fig. 22.13). **More specific detail in regard to indications for surgical intervention for UPJO are covered in Chapter 42.**

Study Name: Renal Scan

FIG. 22.13 (A) Cortical phase of mercaptoacetyltriglycine renal scan. (B) Drainage phase of mercaptoacetyltriglycine renal scan.

Although MAG3 renography appears to be ideal for identifying significant obstruction, a number of pitfalls have been identified. The most significant is an inherent false-positive scan that may occur with the dehydrated patient or when furosemide is given too early in the presence of a capacious system associated with severe dilation of the kidney and/or ureter (Nguyen et al., 2014). Ideally, the diuretic should be administered at the height of uptake, which will vary among patients (Ulman et al., 2000). To mitigate this phenomena, Sussman et al. described a formal upright protocol that appears to address this issue. Secondly, the study is invasive (with both an intravenous and urethral catheter), which negatively affects the patient experience. Finally, the region of interest requires attention to detail, which may affect the drainage curve, specifically when evaluating a severely dilated system that includes both the kidney and ureter.

The exact role of renal scintigraphy in the evaluation of postnatal UTD is not clearly defined. In part because of the aforementioned pitfalls, invasive nature of the study, and reliability for ultrasonography to predict renal preservation (differential function >40%) some have advocated for a selective approach while relying on serial renal ultrasonography in the early postnatal period (Burgu et al., 2012; Erickson et al., 2007; Herndon, 2012).

The role of the dimercaptosuccinic acid (DMSA) scan in evaluation of prenatal UTD is limited. The agent is bound to the proximal tubule with minimal secretion. Its main use is the detection of cortical defects, representative of dysplasia in the absence of infection, in patients diagnosed with VUR; confirmation of the absence of function in patients with suspected MCDK; or to ascertain polar function in patients with duplex collecting systems (British Nuclear Medicine Society, n.d.).

Magnetic Resonance Urography

The role of magnetic resonance urography (MRU) in the evaluation of prenatal UTD is not clearly defined. The main advantages are the lack of radiation while providing superior anatomic detail in addition to the ability to assess differential function, glomerular filtration rate, and drainage (Jones et al., 2004; McMann et al., 2006). The main drawbacks are cost, need for sedation and/or anesthesia, and lack of availability at all centers. One specific barrier for neonates is the need for prone positioning, which may create access issues if emergent airway problems were to develop.

The clinical application is reserved for situations that dictate information

in regard to specific anatomic detail and/or renal function to aid in operative planning such as ectopic ureter, megaureter, or anatomic vascular variants such as lower pole vessels resulting in UPJO (Weiss et al., 2015).

Key Points

- The initial postnatal ultrasound scan should be obtained at 48 hours to account for intravascular depletion that occurs in the initial postnatal period secondary to third spacing, which later becomes mobilized to the intravascular space.
- UTD classification assigns three levels of risk: P1 UTD (SFU 2; low risk) includes APD 10 mm to less than 15 mm and central calyceal dilation; P2 UTD (SFU 3; intermediate risk) includes APD greater than or equal to 15 mm and peripheral calyceal or ureteral dilation that may be in isolation; P3 (SFU 4; high risk) includes APD greater than or equal to 15 mm and/or positive values for other data points such as parenchymal cysts or thinning.
- The degree of APD dilation correlates poorly with the presence and degree of VUR in patients with prenatal UTD.
- Recommendations for VCUG for prenatal UTD should be based on risk for UTI in the absence of concerns for LUTO.

Management Recommendations for Postnatal Urinary Tract Dilation

P1 Urinary Tract Dilation (Low Risk)

Most patients evaluated in the postnatal period will have P1 UTD, and this will represent a transient condition. There has been recent evidence from two large patient registries in regard to risk for UTI, utility of PA, and expected resolution rates for urinary tract dilation (Braga et al., 2015, 2018; Capolicchio et al., 2018; Zee et al., 2016, 2017). Postnatal surveillance of the upper urinary tract should be indexed to the probability of disease progression. **For P1 or SFU 1/2, complete resolution has been demonstrated to occur in most patients between 24 and 48 months** (Braga et al., 2015, 2018; Capolicchio et al., 2018; Zee et al., 2016, 2017)**. Based on this data, it is reasonable to obtain the second postnatal ultrasonography between 3 and 6 months of age.**

Although there is slight discrepancy in associated risk factors for UTI between the SFU Hydronephrosis and McMaster registries, there is uniformity in not recommending PA or VCUG for those at "P1 UTD (SFU 1/2) or low risk" as defined by the 2014 Consensus Statement (Capolicchio et al., 2018; Nguyen et al., 2014; Zee et al., 2016).

P2 Urinary Tract Dilation (Intermediate Risk)

The evaluation and management of patients with P2 UTD is less defined. A recent survey of members of the Society for Pediatric Urology indicated that 24% to 46% of respondents would recommend the use of PA, which varied based on gender and circumcision status. Surprisingly, most participants (78%) would obtain a VCUG and a majority (58%) chose a renal scan to assess differential function and drainage (Jackson et al., 2017). **In the absence of more robust evidence, the recommendation for PA and VCUG is left to the discretion of the treating physician.** In most patients, the VCUG can be performed as an outpatient and combined with renal ultrasonography obtained at the first postnatal visit. **As mentioned earlier, an informed conversation with the family should include the expected rate of UTI, probability of detecting VUR, treatment of VUR, and natural history of disease.**

P3 Urinary Tract Dilation (High Risk)

The evaluation and management of this high-risk group is more defined. Several prospective studies have identified this group to be at most risk for UTI, deterioration of renal function, and need for surgical intervention (Braga et al., 2015, 2018; Capolicchio et al., 2018; Zee et al., 2016, 2017)**. The use of PA, lower urinary tract imaging, and renal scintigraphy are recommended for P3 UTD.** Practice pattern data indicate that most respondents to the Society for Pediatric Urology survey would support this approach (Capolicchio et al., 2018; Jackson et al., 2017; Nguyen et al., 2010, 2014). The second ultrasound scan should be obtained at 1 month and can be combined with a VCUG. On occasion, the consideration for LUTO may dictate other imaging for less severe upper tract dilation such as bilateral ureteral dilation and less severe renal distention. If P3 UTD persists, then a MAG3 renal scan should be obtained and can be combined with VCUG if not obtained previously. In regard to duration of PA in the absence of VUR, it is reasonable to continue until surgical intervention for UPJ or 1 year of age. This age cutoff recommendation is derived from prospective data that indicates most UTIs will occur within the first year of life (Zee et al., 2016).

Considerations for Severe Bilateral Urinary Tract Dilation

The recommendations mentioned in the previous section for timing for the evaluation and management of UTD are specific to isolated cases of unilateral disease. The presence of severe bilateral dilation of the kidney, ureters, and bladder with decreased amniotic fluid are strongly suggestive of BOO. In males, this may be a result of PUV, urethral stenosis, or prune belly syndrome. In females, this may secondary to a ureterocele, which should be associated with other findings such as a cystic bladder lesion. Other conditions such as megacystis or bilateral VUR may demonstrate upper and lower urinary tract dilation but will not be associated with oligohydramnios.

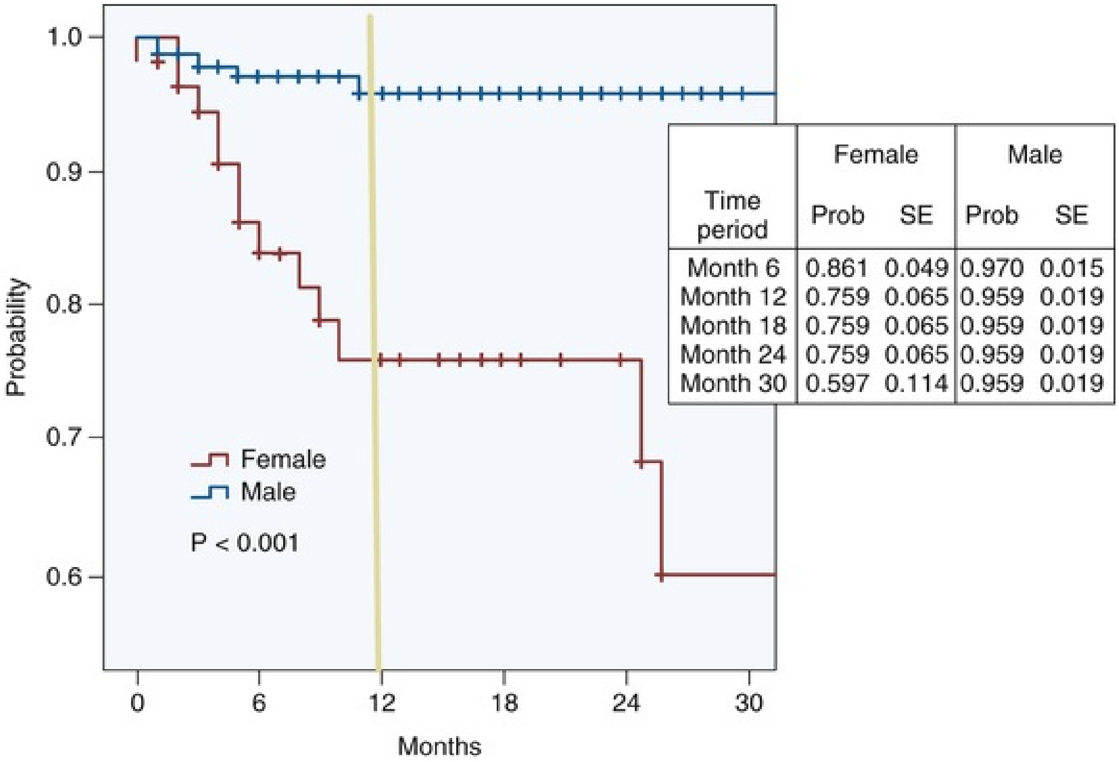
After delivery, it is important to promptly decompress the urinary bladder and begin antibiotic prophylaxis and proceed with prompt evaluation of the urinary tract to determine the etiology.

Key Points

- Complete resolution of P1 UTD should occur in most patients by 4 years of age.
- For P1 UTD (SFU 2), PA and VCUG are not recommended.
- For P2 UTD (SFU 3), the use of PA and VCUG are left to the discretion of the physician.
- For P3 UTD (SFU 4), PA and VCUG are recommended as well as a MAG3 renal scan.

Urinary Tract Infection

UTI will occur in 8% to 22% of patients with prenatal UTD. Recently, associated risk factors for UTI have been described by several retrospective single-center studies and two prospective registries and (Alconcher and Tombesi, 2004; Braga et al., 2013, 2015; Brophy et al., 2002; Coelho et al., 2007; Easterbrook et al., 2017; Estrada et al., 2009; Herndon et al., 1999b; Lee et al., 2006, 2008; Song et al., 2007; Tombesi and Alconcher, 2012; Zareba et al., 2014; Zee et al., 2016). **The degree of kidney dilation is predictive of risk for UTI in patients with prenatal UTD.** In a meta-analysis, Lee et al. demonstrated a linear relationship between the degree of kidney dilation and UTI with a reported incidence of 4%, 14%, 33%, and 40%, respectively for grades 1 to 4 (Lee et al., 2006). In 2007, Coelho reported similar findings in 192 patients that demonstrated a UTI rate of 11%, 18%, and 39% for mild, moderate, and severe hydronephrosis, respectively (Coelho et al., 2007). In 2012, Symanski reviewed 206 patients and showed high-grade kidney dilation significantly predicted UTI with a rate of 13.8% versus 4.1%. In a retrospective review, Herz et al. reported an overall incidence of 22% with high-grade VUR, ureterovesical junction obstruction (UVJO), and ureteral dilation over 11 mm to be predictive of UTI (Herz et al., 2014). Zee et al. reported from the multicenter prospective SFU registry, which prospectively followed 213 patients with prenatal UTD, and demonstrated an overall incidence of 8% of which 89% occurred within the first year of life (Zee et al., 2016) (Fig. 22.14). Multivariant regression analysis revealed female gender, high-grade kidney dilation, and intact foreskin. Braga reported from the McMaster registry, which demonstrated an overall UTI rate of 19% in 334 patients and identified female gender, intact foreskin, high-grade kidney dilation, ureteral dilation, VUR, and lack of prophylaxis to be predictors of UTI (Braga et al., 2015).



Time period	Female		Male	
	Prob	SE	Prob	SE
Month 6	0.861	0.049	0.970	0.015
Month 12	0.759	0.065	0.959	0.019
Month 18	0.759	0.065	0.959	0.019
Month 24	0.759	0.065	0.959	0.019
Month 30	0.597	0.114	0.959	0.019

FIG. 22.14 30-Month event-free survival by gender from date of birth to first urinary tract infection. (Modified from Zee RS, Herbst KW, Kim C, et al. Urinary tract infections in children with prenatal hydronephrosis: A risk assessment from the Society for Fetal Urology Hydronephrosis Registry. *J Pediatr Urol* 12[4]:261.e3 [Figure 2], 2016).

Uniformity exists in identifying female gender, high-grade kidney dilation (P3, SFU 4), and uncircumcised status as factors associated with increased risk for UTI (Braga et al., 2015; Zee et al., 2016)**. Potential factors that deserve further evaluation include ureteral dilation, VUR, and the use of PA** (Braga et al., 2015, 2016; Coelho et al., 2007; Herz et al., 2014). One potential confounder in analysis of these studies is the lack of uniform screening for VUR and severity of illness populated within the various studies.

Prophylactic Antibiotics

The role of PA for the prevention of UTI in patients with prenatal urinary tract dilation is not clearly defined (Alconcher and Tombesi, 2004; Braga et al., 2013, 2015; Brophy et al., 2002; Coelho et al., 2007; Easterbrook et al., 2017; Estrada et al., 2009; Herndon et al., 1999b; Herz et al., 2014; Lee et al., 2006, 2008; Merguerian et al., 2010. Song et al., 2007; Tombesi and Alconcher 2012; Zareba et al., 2014; Zee et al., 2016). Historically, the recommendation for

PA was not evidence based, and thus most patients who were identified with upper urinary tract dilation were placed on PA and evaluated with a VCUG. In part, this approach was based on the known association of VUR with prenatal dilation of the kidney, which could be present in up to 25%, even in those with resolved postnatal dilation (Herndon et al., 1999b; Upadhyay et al., 2003). A systematic review by Braga revealed a significant benefit for PA to reduce UTI for high-grade UTD versus low-grade UTD (28.9% vs. 14.6%, $P = 0.02$) (Braga et al., 2013). The Herz retrospective study reported a similar finding with a 7.9% versus 18.7% rate in those with PA and without PA, respectfully. Although these findings did not meet statistical significance, a fivefold reduction in UTI was demonstrated in a subset of patients with ureteral dilation who were managed with PA (Herz et al., 2014). The two prospective registries have reported divergent findings. The report from the SFU registry failed to demonstrate a reduction in UTI in patients managed with prophylaxis, and the McMaster registry revealed a significant risk reduction (Braga et al., 2015; Zee and Herndon, 2016; Zee et al., 2016). A recent systematic review of 11 studies that included over 3900 patients failed to demonstrate the efficacy of PA to prevent UTI. Pooled UTI rates from the nonrandomized trials ($n = 10$) failed to demonstrate a risk reduction with the use of PA: 7.5% (95% CI, 6.4% to 8.6%) no prophylaxis versus 9.9% (95% CI, 8.4% to 11.4%) prophylaxis (Easterbrook et al., 2017).

A paradigm shift has occurred in regard to the indiscriminate use of PA despite its excellent safety profile (Zee et al., 2016). A meaningful risk reduction for the development of UTI should exist in those in whom PA is recommended. Currently, several barriers exist that inhibit the ability to completely evaluate this impact. Primarily, the low incidence of UTI (8% to 19%) creates a limited number of events that hinders the ability to statistically discriminate PA's impact on risk for UTI. Second, as mentioned earlier, the populations evaluated in these studies are not clearly identified because of the varied use of screening for VUR and administration of PA in patients with prenatal UTD.

Current recommendations restrict the use of PA to those at increased risk for UTI. An evidence-based approach would support those with higher grades of UTD, boys with intact foreskin, females, and selectively those with VUR and/or ureteral dilation. Patient age and hepatic maturity should be factors used to select the appropriate antibiotic, which includes: amoxicillin (newborn and up), first-generation cephalosporins (newborn and up), nitrofurantoin (8 weeks of age and up), and trimethoprim (8 weeks of age and up) derivatives. Recent evidence indicates that a majority of pediatric urologists are supportive of this approach (Jackson et al., 2017).

Key Points

- The degree of dilation is predictive of risk for UTI in patients with prenatal UTD.
- Risk factors for UTI for prenatal UTD include female gender, intact foreskin, high-grade kidney dilation, ureteral dilation, and VUR.
- Prophylactic antibiotics are recommended for those at risk for UTI including P2 UTD (SFU 3) and P3 UT (SFU 4).

Key Conditions

Etiology of Prenatal Urinary Tract Dilation

Prenatal UTD represents a wide spectrum of disease, and a brief overview of common diagnoses will be discussed in the following sections as it pertains to prenatal UTD. (Table 22.4) A more in-depth review can be found in the accompanied respective chapters.

TABLE 22.4

Etiology and Incidence for Antenatal Hydronephrosis

ETIOLOGY	INCIDENCE
Transient urinary tract dilation	50%–70%
Ureteropelvic junction pattern dilation	10%–30%
Vesicoureteral reflux	10%–40%
Ureterovesical junction pattern dilation	5%–15%
Multicystic dysplastic kidney	2%–5%
Duplex system, ureterocele, ectopic ureter	5%–7%
Lower urinary tract obstruction (PUV, PBS)	0.1%%–0.5%

PBS, Prune belly syndrome; *PUV,* posterior urethral valve.

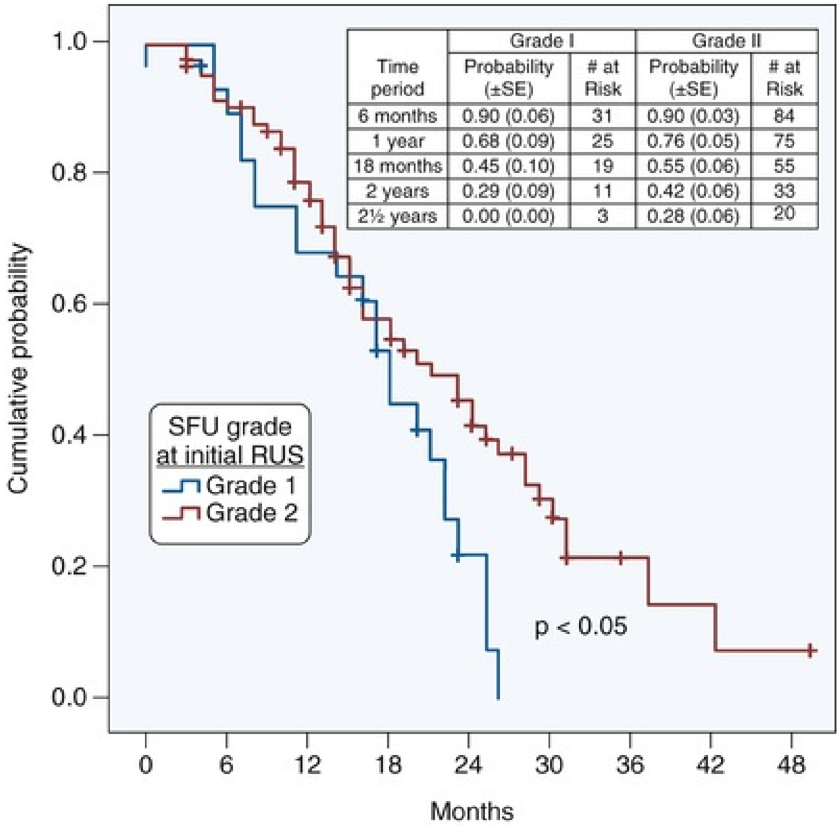
Modified from Nguyen HT, Herndon CDA, Cooper C, et al. The Society for Fetal Urology Consensus Statement on the evaluation and management of antenatal hydronephrosis. *J Pediatr Urol* 6(3):217, Table 5, 2010.

Transient Urinary Tract Dilation

The reported resolution rate for UTD varies throughout the literature ranging from 41% to 88% (Nguyen et al., 2010). As mentioned earlier, the ability to reliably interpret the literature is confounded by multiple factors, mainly inconsistency with use of nomenclature for grading and the lack of uniform screening for VUR. This condition is felt to represent physiologic nonpathologic dilation that demonstrates prenatal resolution rates between 21% and 56% (Adra et al., 1995; Corteville et al., 1991; Mandell et al., 1984). Several studies have demonstrated similar findings and documented postnatal resolution rates of 90% to 98% for patients with “mild” dilation, which likely would be re-classified as normal with the UTD system that accounts for physiologic dilation

(Barbosa et al., 2012; Maayan-Metzger et al., 2011; Zee et al., 2016).

Recently, resolution rates from prospective registries have further defined this population and have given insight to the timing of this event based on longitudinal follow-up. **Braga demonstrated greater than 90% resolution for SFU grade 1 and 2 patients at 12 and 18 months, respectively. Using data from the SFU Hydronephrosis Registry, similar findings were reported by Zee et al. (2017) for SFU grade 1 and 2 patients, which resolved in 100% at 26 months and 95% at 48 months, respectively.** (Fig. 22.15)



Time period	Grade I		Grade II	
	Probability (±SE)	# at Risk	Probability (±SE)	# at Risk
6 months	0.90 (0.06)	31	0.90 (0.03)	84
1 year	0.68 (0.09)	25	0.76 (0.05)	75
18 months	0.45 (0.10)	19	0.55 (0.06)	55
2 years	0.29 (0.09)	11	0.42 (0.06)	33
2½ years	0.00 (0.00)	3	0.28 (0.06)	20

FIG. 22.15 Resolution decay curve for patients presenting with the Society for Fetal Urology grade 1 *(gray)* or grade 2 *(black)* urinary tract dilation. At 2.5 years, the probability of resolution is 100% for grade 1 and 72% for grade 2, and at 4 years it is 95% for grade 2. (Modified from Zee RS, Herndon CDA, Cooper CS, et al. Time to resolution: a prospective evaluation from the Society for Fetal Urology Hydronephrosis registry. *J Pediatr Urol* 13(3):316.e1–316.e5, 2017.

The UTD classification system accounts for physiologic dilation of the renal pelvis, which should reduce the frequency of postnatal testing for UTD. It is well established that most patients with P1 UTD will resolve within 4 years (Zee et al., 2017). **One caveat is that some of these patients will have undiagnosed VUR, and both the parents and practitioner should be aware of this possibility, which can be seen in up to 31% of patients** (Adra et al., 1995; Herndon et al., 1999b; Upadhyay et al., 2003).

Ureteropelvic Junction Obstruction Pattern of Dilation

UPJO represents the most common surgical entity associated with prenatal UTD. The degree of prenatal UTD demonstrates a linear relationship with the development of the UPJO pattern of dilation (Lee et al., 2006). This represents a spectrum of disease with the more severe form undergoing more intensive imaging, which may clarify those patients who should be considered for surgical intervention. For the purposes of this chapter, we will restrict the discussion to those patients who demonstrate P2/P3 disease, which equates to SFU 3/SFU 4 or moderate/severe disease.

Several reports have demonstrated a prenatal APD threshold that is predictive of patients in whom surgery is performed for the UPJO pattern of dilation. The allowable degree of APD affects the sensitivity of detecting UPJO. As the limit is lowered, more nonobstructive conditions will be folded into this category. Several studies have identified a prenatal or postnatal APD that is predictive of UPJO (Alexander et al., 2015; Coplen, 1997; Dhillon, 1998; Shamshirsaz et al., 2012).

Following the work of Dhillon at Great Ormond Street, **Coplen demonstrated that a 15-mm APD threshold provided an acceptable sensitivity of 73% and a specificity of 82% for predicting those patients in whom surgical intervention was performed.** In evaluation of 257 neonates, 195 (76%) were observed with nonobstructive dilation with a mean APD of 11.8 mm. A total of 62 of 257 (24%) patients required surgical intervention, and the mean APD was statistically greater at 22.3 mm. The receiver operating characteristic curve for predicting surgical intervention was 15 mm, which identified obstruction in 80% of patients (Coplen, 1997). Finally, using data from the SFU registry, Shamshirsaz reviewed 53 patients with prenatal UTD identified in the second trimester (Shamshirsaz et al., 2012). This group identified separate APD thresholds for both the second and third trimesters. An APD of 9.5 mm for the second trimester and an APD of 15 mm for the third trimester were both predictive of those patients in whom surgical intervention was performed. In looking at postnatal APD, Burgu et al. reported a 20-mm threshold to be predictive of preservation of renal function in early neonatal UTD (Burgu et al., 2012).

A more recent meta-analysis consisted of five studies comprising 1159 patients and evaluated the threshold of 15-mm APD as a predictor for those in whom surgical intervention was deemed necessary. Pooled analyses with a 95% CI revealed a sensitivity of 0.81, specificity of 0.78, 3.73 positive likelihood ratios, and 0.24 negative likelihood ratios. The odds ratio for 15-mm APD to predict surgical intervention was 13.33. The postnatal APD was a significantly better predictor of surgical intervention when compared with prenatal APD (Zhang et al., 2018).

Although APD measurement is objective, it is dependent on factors such as patient position, hydration status, and degree of bladder fullness. Sharma et al. reported that position change (prone vs. supine) may be predictive of identifying patients who need surgical intervention for UPJ. When the measurement of APD decreased when measured in the prone versus supine position, 7 of 16 (43%) with APD of 30 to 40 mm and 11 of 15 (73%) with APD of 15 to 30 mm were observed without the need for surgery (Sharma et al., 2012).

The clinician should be aware that severe UTD does not equate to surgery in all patients. Ulman et al. (2000) reported outcome on 104 patients with severe UTD in whom surgery was performed in 23 (22%). Resolution occurred in 72 of 104 (69%) patients who were followed nonoperatively at a mean of 2.5 years.

The SFU grading system is equally successful in predicting differential renal function and identifying those patients who undergo surgical intervention for UPJO. Erickson demonstrated that 33 of 33 patients with SFU grade 3 UTD demonstrated preserved function on renal scintigraphy used to evaluate UPJO (Erickson et al., 2007). Ross et al. used this system to group patients into those who require early neonatal intervention. A retrospective review identified 125 patients with SFU grade 3 and 4 UTD. Early intervention was performed in 27 of 125 patients of whom 89% had SFU grade 4. Observation continued in 77 of 125 patients of whom 78% demonstrated SFU grade 3 (Ross et al., 2011).

Therapeutic intervention for UPJO is highly successful and is discussed in detail in Chapter 42. In brief, both open and minimally invasive surgical intervention demonstrated a success rate of 97% to 100% (Cain et al., 2001; Herndon et al., 2013; Minnillo et al., 2011; O'Brien and Shukla, 2012; Paradise et al., 2017; Sweeney et al., 2011). Practice pattern data suggest a threshold of 2 years of age when a majority of pediatric urologists would consider a minimally invasive approach toward the correction of UPJO (Jackson et al., 2017). However, efficacy has been demonstrated in infants younger than 6 months of age (Paradise et al., 2017).

Recommendations for Ureteropelvic Junction Obstruction Pattern of Dilation

A majority of patients will be followed without the need for surgical intervention postnatally. A postnatal ultrasound scan should be performed in the early neonatal period in those with P2 or P3 UTD. Prophylactic antibiotics may be considered with more severe forms of dilation (P3/SFU 4) because of the increased risk for UTI. Lower urinary tract imaging is recommended as well to exclude VUR and assure normalcy of the posterior urethra in males. The use of renal scintigraphy is left to the discretion of the physician and should be used for persistent P3 UTD because of its high correlation for the need of early surgical intervention. The timing of this study remains debated. A “well-tempered” baseline study can be performed at 1 month for severe disease. However, a practical approach has been recommended with consideration of serial ultrasonography to determine the fate of the obstruction. If P2 UTD and/or APD measures less than 20 mm, then normal differential function should exist, thus obviating the need for surgery. Neither approach is evidence based, and the practitioner should employ the practice with which he or she is most comfortable. **Recommendations for the consideration for surgery for UPJO include increased APD and urinary tract dilation on serial ultrasonography; decreased differential function (<40%) and/or a delayed drainage curve; or increased retention of radiotracer on delayed upright imaging on MAG3 renal scan.**

Vesicoureteral Reflux

VUR has been reported in up to 31% of patients screened with prenatal UTD (Adra et al., 1995; Herndon et al., 1999b; Lee et al., 2006; Nguyen et al., 2010; Upadhyay et al., 2003**). A systematic review of the literature by Lee et al. (2006) demonstrated that the grade of prenatal UTD correlates poorly with the severity of VUR.** Historically, screening for VUR was pursued because of the relatively high probability of detecting reflux. However, a change in the concept of VUR has become apparent with two phenotypes presenting clinically.

A majority of VUR cases present in girls with febrile UTI (fUTI) and are less associated with renal scarring and high-grade disease in comparison with VUR that is detected through screening of prenatal UTD, which is more common in boys and represents high-grade disease, with up to 40% of patients demonstrating renal dysplasia in the absence of UTI (Herndon et al., 1999b, 2001) (Fig. 22.16). Fortunately, this latter group demonstrates a low rate of UTI when circumcised and enjoys much higher resolution rates compared with published rates of resolution, perhaps related to delayed maturation of the bladder neck that resolves after 1 year of age. This clinical difference has lead to recommendations for less aggressive screening in the absence of UTI (Yeung et al., 1998). In 1999, prospective outcome data from three medical centers reviewed 71 patients (56 male) confirmed with postnatal VUR. Increase in kidney dilation with voiding was seen in 4 patients, and ureteral dilation was only seen in 15 patients (26 ureters). The initial postnatal ultrasound scan was normal in 25% of patients. VUR was bilateral in 36 of 56 males and 9 of 15 females. A UTI developed in 10 of 19 (53%) boys with intact foreskin. Surprisingly, 15 of 74 high-grade refluxing units resolved at an average age of 0.9 and 2.1 years for boys and girls, respectively. Other centers subsequently published similar results (Upadhyay et al., 2003). Of note, pooled resolution outcomes data from the 2010 AUA VUR guidelines failed to demonstrate a significant increased rate of resolution for prenatally identified VUR despite an overall resolution rate of 50% (Peters et al., 2010).

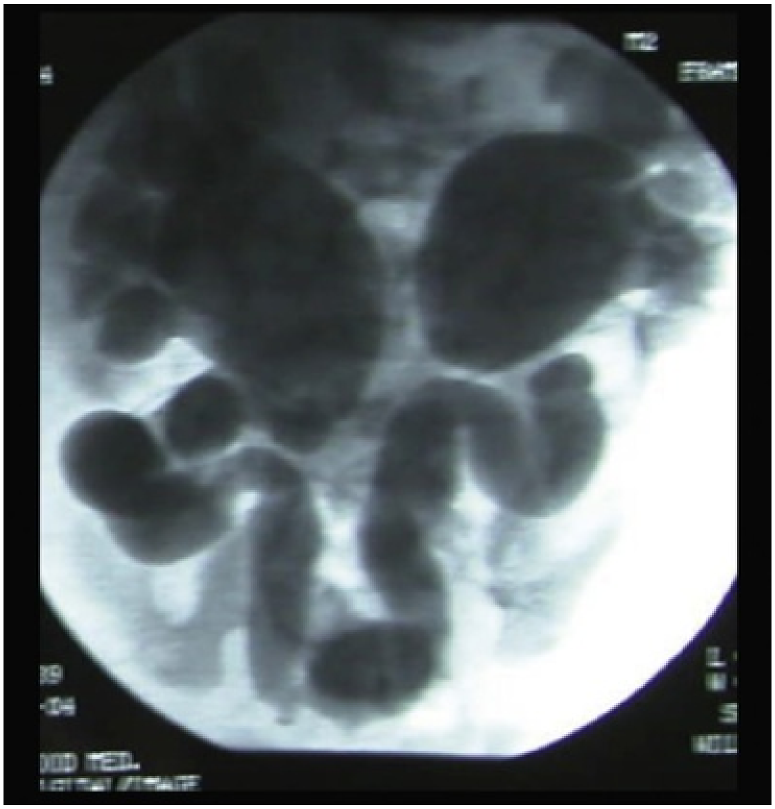


FIG. 22.16 Bilateral grade V vesicoureteral reflux in a patient with P1 urinary tract dilation (Society for Fetal Urology 2).

Whether prenatally detected VUR is a risk factor for UTI is debatable. Two large prospective registries have come to divergent opinions in this regard. The McMaster group demonstrated VUR to carry a significantly increased risk for fUTI. Males represented 78% of 334 patients enrolled overall. High-grade UTD was seen in 57% of the group. The overall rate of UTI was 19%. VUR was identified in 57 of 238 screened patients (43 of 57 [75%] high grade) of whom two-thirds were maintained on prophylaxis. Zee et al. demonstrated a dichotomous finding using multicenter data from the SFU Hydronephrosis registry. In review of 213 patients with prenatal UTD (154 of 213 [72% male]), high-grade UTD was present in only 26%. VUR was identified in 25 of 133 (19%) of 133 of 213 (62%) screened. The overall rate of UTI was 8%, and neither VUR nor ureteral dilation were associated with UTI. A critical review of these two registries demonstrates different rates of high-grade UTD, screening rates for VUR, and treatment with prophylaxis. This may be a result of regional referral practice pattern variation and implicit bias at each medical center in regard to the benefit of screening and prophylaxis. Nonetheless, the differing rates of UTI for VUR may in part be a result of comparison of different cohorts.

Practice pattern data for pediatric urologists suggest that gender, foreskin status, and grade of UTD affect recommendations for PA and VCUG that ranged from 26% to 57% and 85% to 88% for moderate- and high-grade UTD, respectively (SFU 3/4, P2/3) (Fig. 22.17).

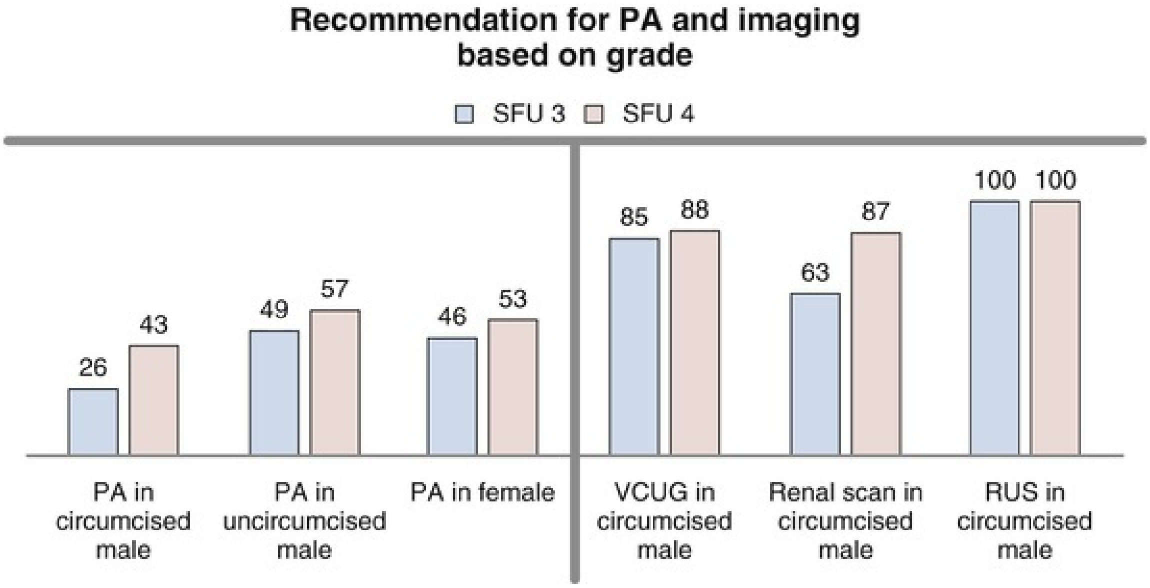

FIG. 22.17 Practice pattern recommendations for antibiotics, voiding cystourethrogram, and renal scintigraphy for members of Society for Pediatric Urology for a 1-month-old patient with Society for Fetal Urology (SFU) 3 or SFU 4 urinary tract dilation. (Modified from Jackson JN, Zee RS, Martin AN, et al. A practice pattern assessment of members of the Society of Pediatric Urology for evaluation and treatment of urinary tract dilation. *J Pediatr Urol* 13(6):604 [Figure 1], 2017).

Recommendations for Vesicoureteral Reflux

VUR is common in patients with a history of prenatal UTD. A reasonable approach would account for the risk for UTI to be the basis for screening. For example, females with high grade UTD or males with intact foreskin are at high risk for UTI and should be screened as opposed to circumcised males with low-grade UTD. An informed discussion concerning the natural history of VUR and costs/benefits of prophylaxis should occur between patients and providers.

Megaureter/Ureterovesical Junction Obstruction

Primary congenital megaureter is a less common cause for prenatal UTD and has been classified as obstructed, nonobstructed, refluxing, and refluxing/obstructed. Postnatally, it can be differentiated from a single-system ectopic ureter, which is usually associated with renal dysplasia and ureteral insertion distal to the bladder neck or vagina.

Several reviews have confirmed that a majority of patients can be followed without the need for surgical intervention. Shukla et al. reviewed the Children's Hospital of Philadelphia experience of 40 patients (Shukla et al., 2005). With a mean of 7 years, 50% of patients resolved urinary tract dilation. A secondary cohort of 10 patients were followed for a mean of 13.4 years. In this group, 4 patients demonstrated resolution, and 1 patient unfortunately experienced renal deterioration requiring nephrectomy. McLellan et al. reviewed the Boston Children's hospital experience in 54 patients with a mean follow-up of 2 years. Resolution was demonstrated in most patients (72%) and identified those with a ureteral diameter of 1.32 cm at increased risk for the need for surgical intervention (McLellan et al., 2002). Chertin et al. reported similar findings with surgical intervention in 31% at a mean follow up of 14.3 months with renal function of less than 30% and ureteral diameter of less than 1.33 cm as predictors of the need for surgery (Chertin et al., 2008). More recently using prospective data, Braga et al. reviewed 80 patients and demonstrated that ureteral diameter appeared to predict the need for surgery in 19 (24%) patients with a mean ureteral dilation of 17 mm versus 12 mm in the nonoperative group ($P = 0.04$). Overall, 76% of patients resolved at a mean follow-up of 19 months (Braga et al., 2016).

Recommendations for Megaureter

Postnatal renal/bladder ultrasonography and institution of PA should be performed shortly after birth. A VCUG should also be obtained to better classify the megaureter. Recently, the British Association of Pediatric Urologists published the following appropriate guidelines in a Consensus Statement:

1. Evaluation: Ureteral diameter of greater than 7 mm after 30 weeks as threshold for postnatal renal ultrasonography, initiation of PA, VCUG in all patients with special consideration for timing in those suspected to potentially have PUV, and consideration of renal scintigraphy to assess function and obstruction at the level of the ureterovesical junction (UVJ).
2. Surgical Intervention: Required in a minority and reserved for decreased

renal function (<40%), fUTI, or pain. Temporizing procedures such as cutaneous ureterostomy, cutaneous pyelostomy, or refluxing ureteral reimplantation should be performed for patients younger than 1 year of age. Ideally, the procedure should be deferred until 1 year of age and allow for a definitive ureteral reimplantation.

3. Follow-up: The British Association of Pediatric Urologists recommends long-term follow-up into adulthood because of the risk for late asymptomatic deterioration (Farrugia et al., 2014).

Lower Urinary Tract Obstruction (Posterior Urethral Valve, Prune Belly Syndrome, Urethral Stenosis/Atresia)

The prenatal detection of LUTO can be made with the constellation of oligohydramnios, bladder distention, and the lack of cycling on prenatal ultrasonography and varying degrees of ureteral and kidney dilation that may be severe and associated with cystic changes (Fig. 22.18). It is difficult to establish the exact diagnosis based on imaging alone in that PUV, urethral stenosis/atresia, and prune belly syndrome may present with a similar clinical picture. **Significant compression of the thoracic region from bladder distention coupled with decreased amniotic fluid may lead to immediate need for pulmonary resuscitation. Patients at highest risk are those in whom oligohydramnios was detected before 27 weeks' gestational age** (Mandell et al., 1984). Various prenatal features may favor a system under tension and present with "pop-offs" such as urinary ascites (secondary patent urachus), perirenal urinoma (Fig. 22.19), and VUR. These findings and the "keyhole" sign may favor the diagnosis of PUV or urethral atresia (Fig. 22.20). However, the only reliable method to determine the etiology is through direct visualization with fetal cystoscopy (Morris et al., 2011; Quintero et al., 1995; Ruano et al., 2010, 2011, 2015; Sananes et al., 2016). **As mentioned earlier in this chapter, with prenatal counseling, a narrow window between 18 and 24 weeks is the ideal time to consider intervention, which should be preceded by extensive counseling in regard to the expected benefits in relation to the relatively high complication rate** (Elder et al., 1987; Farrugia, 2016; Morris et al., 2013b). After delivery, the urologic team should be immediately on hand to aid in bladder decompression. The diagnosis of PUV can be distinguished from prune belly syndrome because of the lack of abdominal musculature and bilateral nonpalpable testes, which will be apparent on physical examination in the latter. A 5-Fr feeding tube should be placed into the urinary bladder and confirmed with a KUB scan, as some patients with a dilated posterior urethra may initially drain urine. Digital rectal pressure may be needed to direct the drainage catheter over the high riding bladder neck in some patients. **The neonatal team should be advised to avoid using a balloon catheter as it may drop down into the**

posterior urethra and obstruct or damage the urethra and impair drainage of the ureteral orifices (Jordan and Hoover, 1985). If one cannot pass a catheter into the urethra, then a percutaneous suprapubic catheter can be placed with ultrasound confirmation at the bedside using local anesthesia and an angiocatheter using the Seldinger technique.

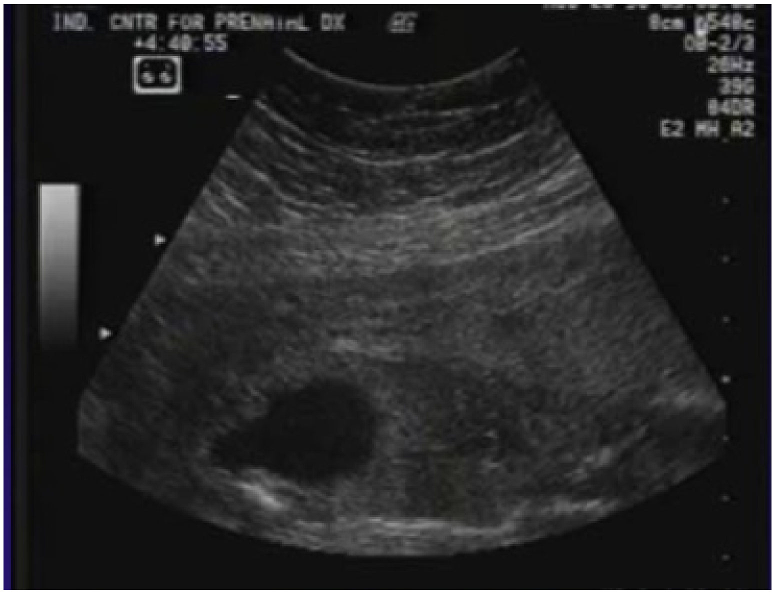

FIG. 22.20 Prenatal ultrasound scan demonstrating “keyhole” sign indicative of lower urinary tract obstruction.

Posterior Urethral Valves

PUV represents the most common form of LUTO and afflicts between 1.4 and 2.2 per 10,000 births (Anumba et al., 2005; Malin et al., 2012). This condition appears to be more common in minority ethnic groups. The diagnosis can be made by physical examination and lower urinary tract imaging (Fig. 22.21). **Unfortunately, the ability to identify this condition prenatally does affect the natural history of this condition with about one-third developing the need for long-term renal replacement. Chapter 33** discusses the evaluation and management of PUV in more detail.

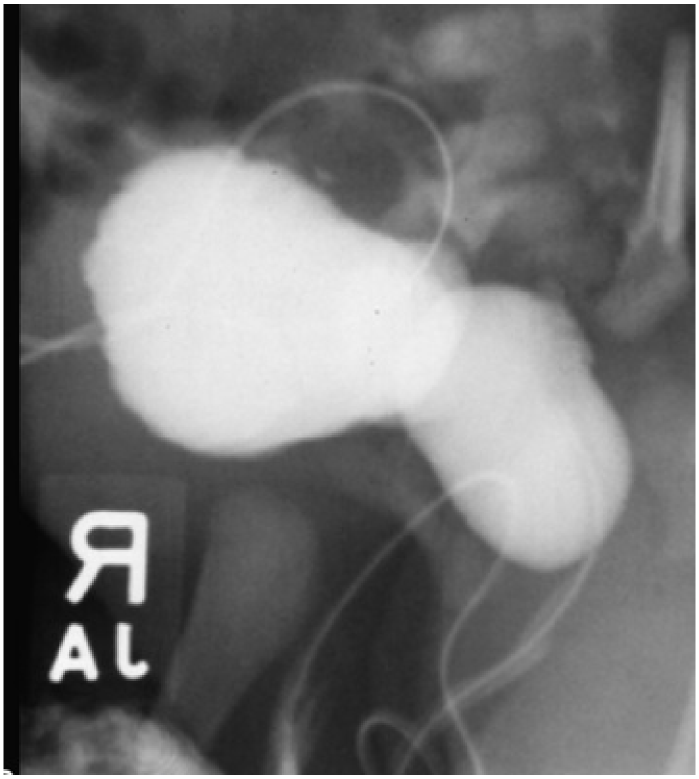

FIG. 22.21 Voiding cystourethrogram demonstrating a dilated posterior urethra consistent with the diagnosis of posterior urethral valves.

Prune Belly Syndrome/Megalourethra

The constellation of massive dilation of the bladder (megacystis) and upper urinary tract combined with the physical examination findings of absent/decreased rectus abdominal wall musculature with bilateral nonpalpable testes confers the diagnosis of prune belly syndrome (see Chapter 32 for a more detailed description). This condition may be associated with urethral atresia in which there may be associated oligohydramnios and clinical outcome similar to PUV. Additionally, congenital megalourethra may occur with this condition as well.

Urethral Stenosis/Atresia

Urethral stenosis and/or atresia more commonly resides with the constellation of signs that include oligohydramnios, severe bilateral urinary tract dilation, and bladder distention. Postnatally, a catheter will not pass into the bladder, and a narrowed penile urethra with a membrane at the level of the membranous/prostatic urethra can be seen on cystoscopy. Urinary diversion with a vesicostomy will be required initially but can be used to facilitate the PADUA (progressive augmentation by dilating the urethra anterior) procedure (Stalberg and González, 2012).

Congenital Megacystis

Two forms of congenital megacystis have been described. Massive reflux results from laterally displaced ureteral orifices that leads to cycling of refluxed urine and a resultant dilated urinary bladder that is often very thin. Surgical correction of the reflux will restore bladder dynamics (Burbige et al., 1984). The more lethal form occurs in association with microcolon-intestinal hypoperistalsis syndrome. Most children will require urinary diversion with vesicostomy or intermittent catheterization. Rarely do patients live past 1 year of age (Bloom and Kolon, 2002).

Recommendations for Lower Urinary Tract Obstruction

A baseline renal/bladder ultrasound scan should be performed and used as a guide after an interval of decompression. The neonatal team should be advised against performing an immediate VCUG in patients with renal insufficiency who require bladder decompression as it may be difficult to replace the catheter. The period of recommended bladder decompression will vary depending on the timing of the serum creatinine nadir. Some children may experience an initial increase in serum creatinine resulting from intravascular volume depletion and under-resuscitation. Equally, the neonatal team should be advised of the likely concentrating defect inherent with these disease processes that may be exacerbated with a postobstructive diuresis. The clinician should be aware that some patients may experience oliguria or even anuria after initial bladder decompression as the hypertrophied bladder wall creates resistance that initially is difficult to overcome with a tortuous dilated upper urinary tract (Fig. 22.22). This can be mitigated with antimuscarinics. A repeat ultrasound scan should be obtained to serve as a baseline for maximal decompression following intervention. A VCUG can be obtained at this point to guide in surgical management, which is discussed in more detail in Chapter 33.

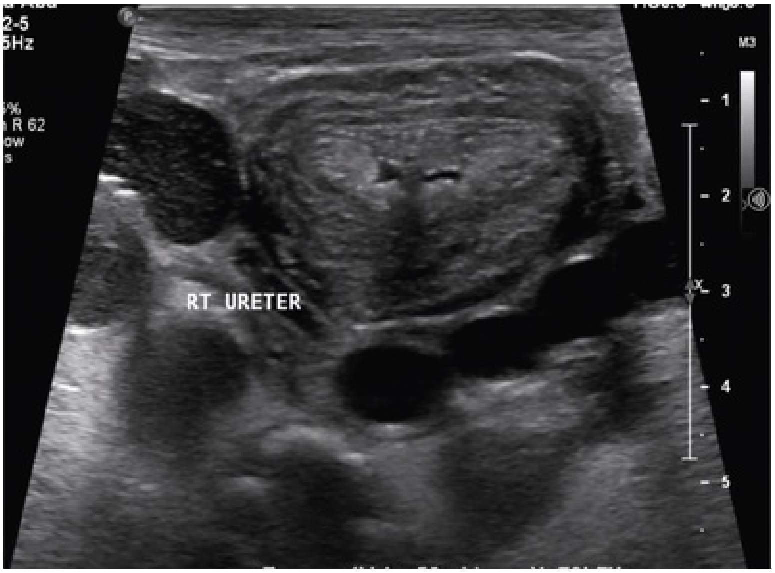

FIG. 22.22 Transverse ultrasound image of the bladder demonstrating marked thickening of the urinary bladder after decompression and associated bilateral distal ureteral dilation.

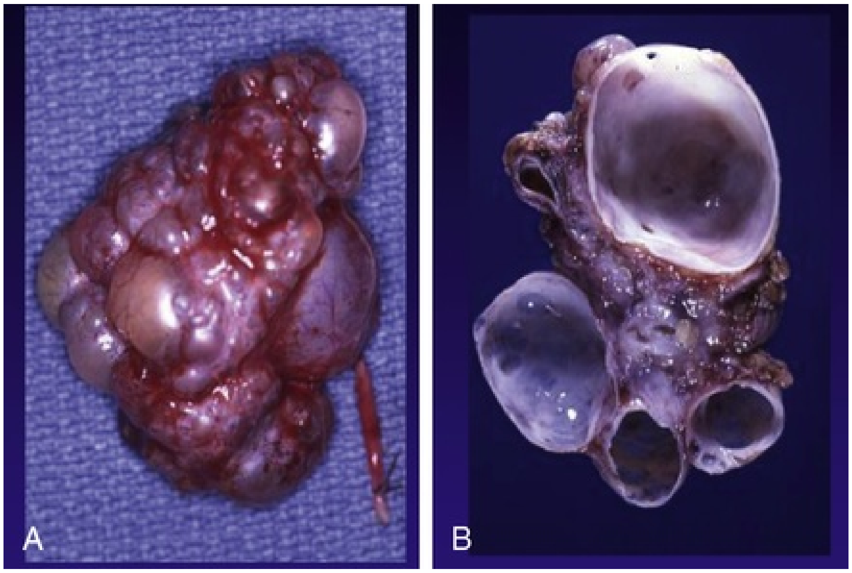
Kidney Anomalies

Multicystic Dysplastic Kidney

The majority of cystic disease that presents prenatally will not require surgical intervention or affect overall renal function. The clinical implications of MCDK are presented briefly in this chapter with a more in-depth review of the pathophysiology and other cystic diseases found in Chapter 38.

Prenatally, MCDK may be confused for P3 UTD, and thus a critical review of postnatal imaging is warranted. Debate exists as to whether this disease represents a severe obstruction that occurs on the continuum very early prenatally. Although classically multiple cysts in varying sizes are seen in the absence of a large central cyst, other more reniform phenotypes have been described (Fig. 22.23AB). Associated findings that occur in conjunction with MCDK include VUR, which may occur in 20%, and contralateral UPJ (Al-Khaldi et al., 1994; Atiyeh et al., 1992; Heikkinen et al., 1980).



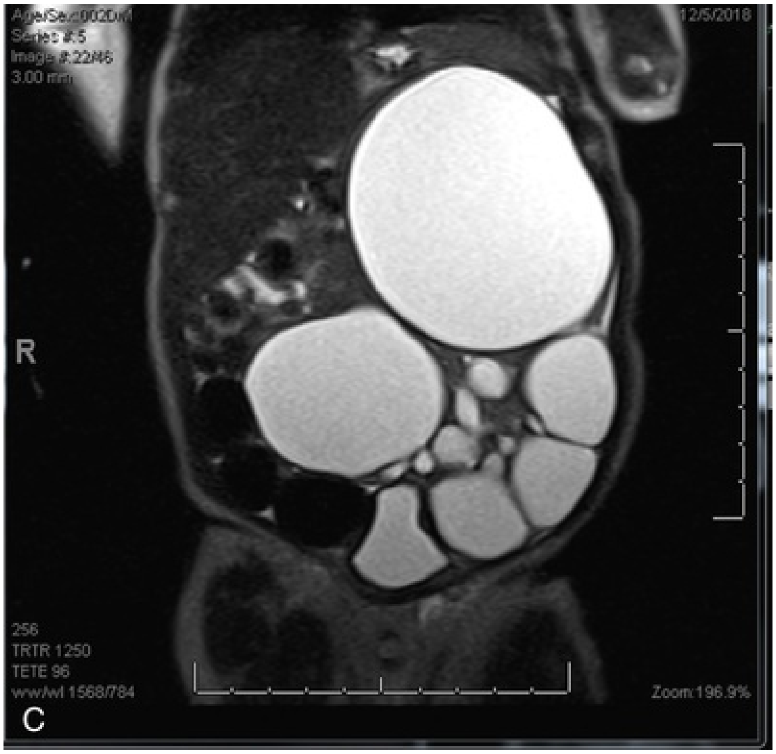


FIG. 22.23 (A and B) Image of non-functional cystic kidney that is reniform shape. (C) Magnetic resonance imaging demonstrating large multicystic dysplastic left kidney with multiple varied sized noncommunicating cysts.

The postnatal evaluation should include renal ultrasonography to substantiate the prenatal findings that were consistent with MCDK. Historically, lower urinary tract imaging to screen for VUR and DMSA renal scintigraphy to confirm the absence of function in the affected kidney were recommended. However, recently the utility of this approach has been challenged, although long-term outcome data are not available. Calaway retrospectively reviewed 133 patients with MCDK who were screened with a VCUG and found VUR present in 23 (17%). Of this group only 4 required surgical intervention. None of the patients with VUR followed without prophylactic antibiotics developed an fUTI (Calaway et al., 2014). From the same center, the ultrasound diagnosis of MCDK demonstrated a 100% correlation with this finding on renal scintigraphy in 84 patients with a normal bladder on ultrasonography (Whittam et al., 2014).

Historically, simple nephrectomy was recommended and based in part on the suspected risk for tumor development in a cystic kidney. However, Narchi conducted a systematic review of the literature that included 26 articles representing 1041 children with MCDK and failed to demonstrate a correlation between MCDK and Wilms tumor (Narchi, 2005). Serial ultrasonography is used to follow involution of cyst and assure normalcy and expected compensatory hypertrophy in the contralateral kidney. Of note, in a health cost analysis, Perez et al. demonstrated that early nephrectomy would be the most efficient therapy in treating these patients. However, this presumption in part assumed long-term follow-up with serial imaging (Pérez et al., 1998).

Recommendations for Multicystic Dysplastic Kidney

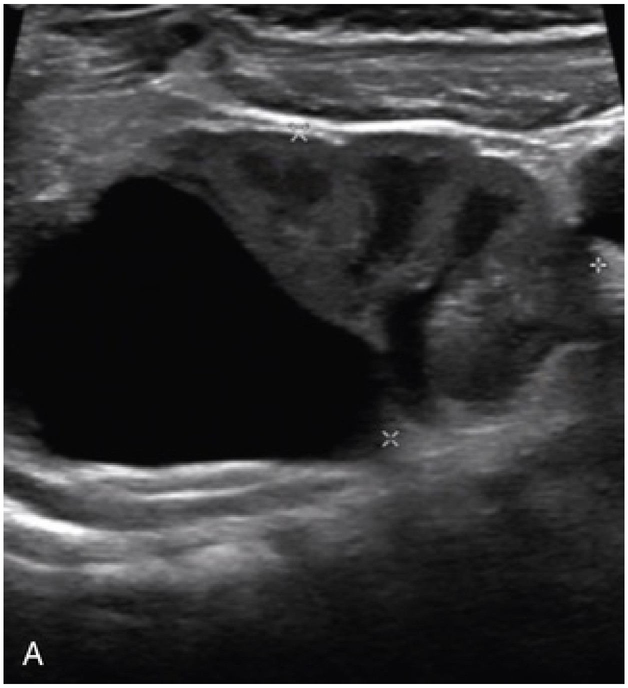
A postnatal renal/bladder ultrasound scan should be performed in the early postnatal period to confirm the prenatal findings. Currently, PA are not recommended because of the low risk for UTI. The decision to pursue a VCUG and DMSA is recommended with the caveat that this is not evidence based and the decision to refrain from these studies is acceptable practice. Future long-term prospective outcome studies are needed.

In the setting of a functional solitary kidney, blood pressure measurement, assessment of proteinuria, and the consideration of yearly ultrasonography should be pursued through puberty to monitor for hyperfiltration injury that may occur with compensatory hypertrophy. Of note, the consideration for serial imaging is not evidence based but in part designed to ensure consistent follow-up for this population that may be at increased risk for renal disease in adulthood. Complete involution of the affected cystic kidney should occur over this interval, and persistent cystic kidneys with a solid component may be considered for surgical removal.

Duplication Anomalies/Ureterocele/Ectopic Ureter

The prenatal identification of duplication anomalies typically occurs as a result of the obstruction of the upper pole moiety that follow the Meyer-Weigert rule. Dilation of the upper pole ureter can be seen and differentiated from the lower pole. A duplication anomaly should also be suspected in the setting of ureteral dilation that is greater than associated renal pelvis dilation. (Fig. 22.24). Cystic changes to the dysplastic upper pole may also be present. On occasion, prenatal ultrasonography may detect a cystic mass within the bladder that is more easily identified on postnatal bladder ultrasonography, which differentiates a ureterocele from an ectopic ureter. This may be difficult at times when the ureterocele opening is ectopic within the bladder neck (Chertin et al., 2003;

Godinho et al., 2013; Quintero et al., 2001). In a female, this may lead to LUTO with associated findings of oligohydramnios seen prenatally (Fig. 22.25). Ureterocele disproportion is a rare condition in which a large ureterocele is identified on bladder ultrasonography with minimal upper urinary tract dilation (Share and Lebowitz, 1989). **VUR is a common finding and equally follows the Meyer-Weigert law in which the upper pole moiety will insert more distally in the bladder with the lower pole moiety inserting more cephalad and lateral, which favors VUR** (Fig. 22.26). Most duplication anomalies will occur in females and are bilateral.



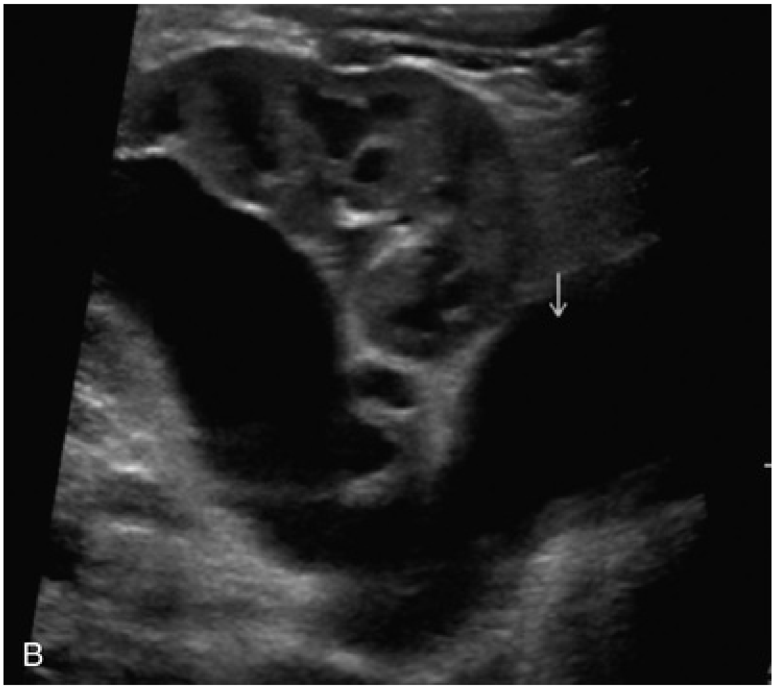


FIG. 22.24 (A and B) Upper pole ureteral dilation *(arrow)* that is more profound than renal pelvis suggestive of duplex system.

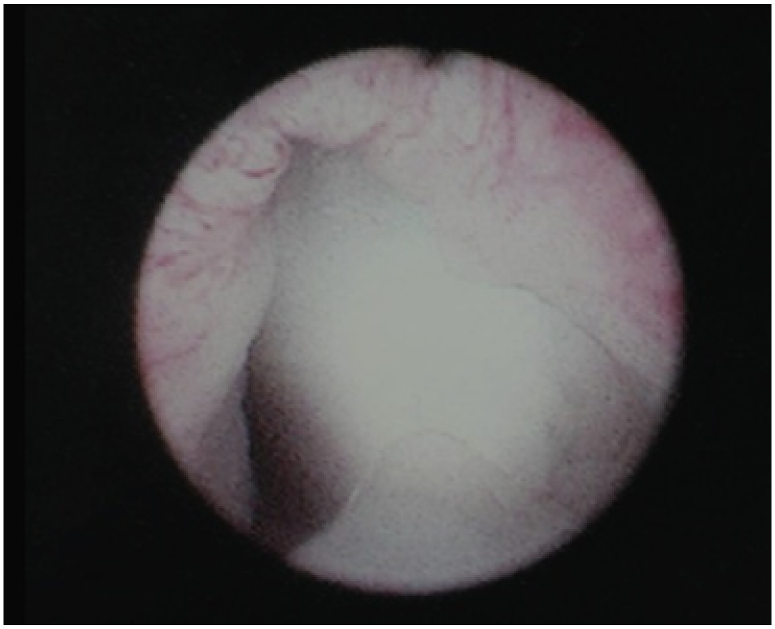

FIG. 22.25 Cystoscopic appearance of bladder outlet obstruction caused by ball-valving ureterocele.

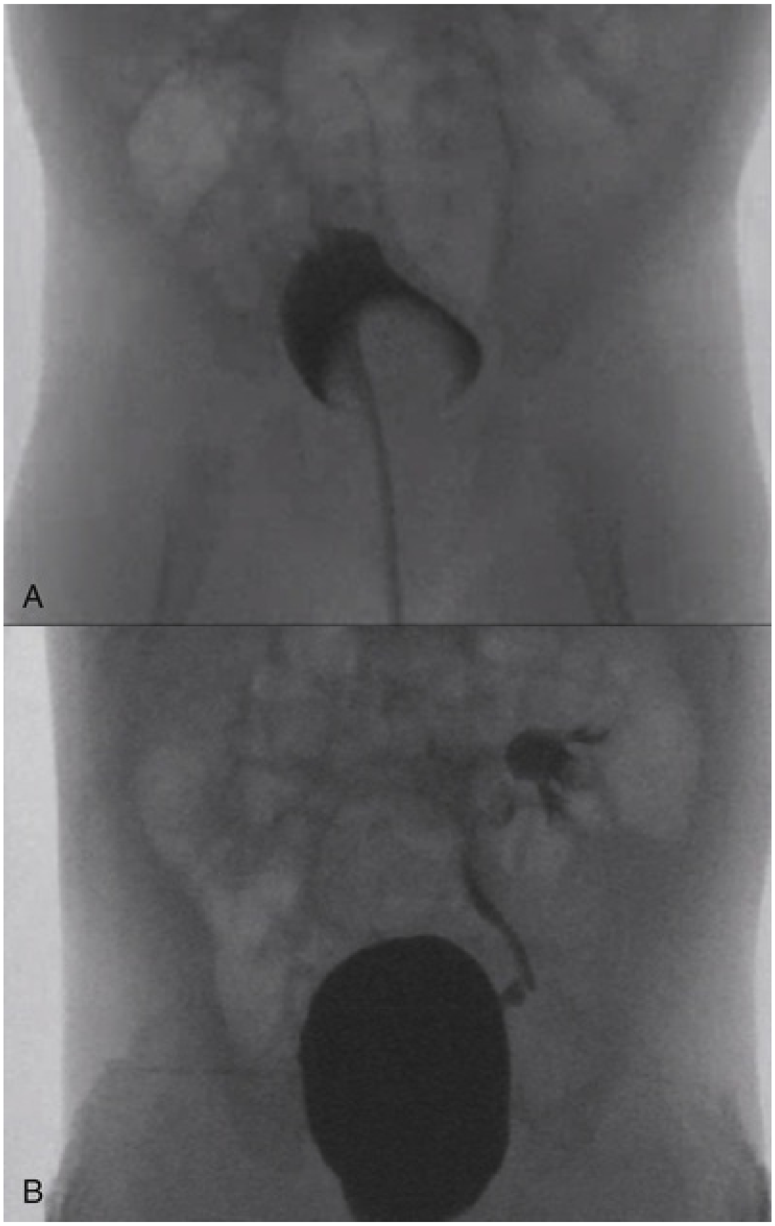

FIG. 22.26 (A) Filling defect on voiding cystourethrogram consistent with ureterocele. (B) “Drooping lily” consistent with lower pole vesicourethral reflex associated with a duplex system.

Postnatal ultrasonography should guide the clinician toward the correct diagnosis in most cases. **A ureterocele can be differentiated from an ectopic ureter based on the thickness of the cystic wall within the bladder. An ectopic ureter that infringes on the bladder may distort the bladder, but the wall of both the bladder and ureter will create two distinct structures** (Fig. 22.27).

FIG. 22.27 (A) Bladder level ultrasound image demonstrating ectopic ureter with clear bladder muscle tissue plane between the ureter. (B) Bladder level ultrasound image with cystic dilation within the bladder consistent with ureterocele.

Initial management may involve puncture of the ureterocele, but this approach is not absolute. Prenatal puncture to address BOO has been successfully described, but the need for this experimental treatment is rare (Quintero et al., 2001). Traditionally, decompression of the ureterocele is reserved for BOO or sepsis. However, recent practice patterns appear to support an elective role as first-line therapy despite the creation of reflux (Chertin et al., 2003, 2007; Jesus et al., 2011). Furthermore, some centers have supported a “watchful waiting” approach (Direnna and Leonard, 2006).

The primary objective for treatment of duplex systems with ureterocele or ectopic ureter should be directed at preservation of the lower pole moiety. This may involve an upper or lower urinary tract approach. In brief, the upper pole approach may involve nephron sparing or ablative methods, both of which have recently gained popularity with a minimally invasive approach (Mason et al., 2014; McLeod et al., 2014; Storm et al., 2011). The decision with regard to preservation of the upper pole is left to the discretion of the physician, as neither practice is evidence based. Long-term data confirm that most patients with an ectopic ureter can be managed with upper tract surgery alone (De Caluwe et al., 2002). The lower pole approach involves a common sheath ureteral reimplantation (both upper and lower moieties for duplex systems) and is reserved for those at most risk for UTI or high-grade VUR to the lower pole. Hussmann reported long-term follow-up and demonstrated the degree and presence of VUR predicted the need for surgery. In the Mayo experience, the absence of VUR afforded an entirely upper pole approach in all patients without VUR, low-grade VUR resulted in surgery in 40% as the result of UTI, and ureterocele excision was required in 96% of patients with high-grade VUR (Husmann et al., 1995).

Recommendations for Duplex Anomalies

In patients suspected of a ureterocele, an examination of the introitus should ensure the absence of a cystic mass that would correspond to a prolapsed ureterocele (Fig. 22.28). **A postnatal ultrasound scan should be performed shortly after birth with specific attention toward evaluation of the urinary bladder. PAs should begin at birth, as well as the characterization of VUR, size of the ureterocele, and an assessment for BOO. Renal scintigraphy may play a role in evaluating the degree of upper pole function, which may aid in surgical decision-making.** Generally speaking, the degree of VUR and upper moiety function will dictate treatment. For example, in a female patient with a ureterocele who is found to have high-grade VUR to the lower pole and preserved upper pole function, an initial incision would be appropriate given the high likelihood and need for lower urinary tract surgery based on the risk for UTI. For a male patient with no evidence of VUR and dysplastic changes to the upper pole, an upper pole approach may be appropriate with either renal preservation or ablation.

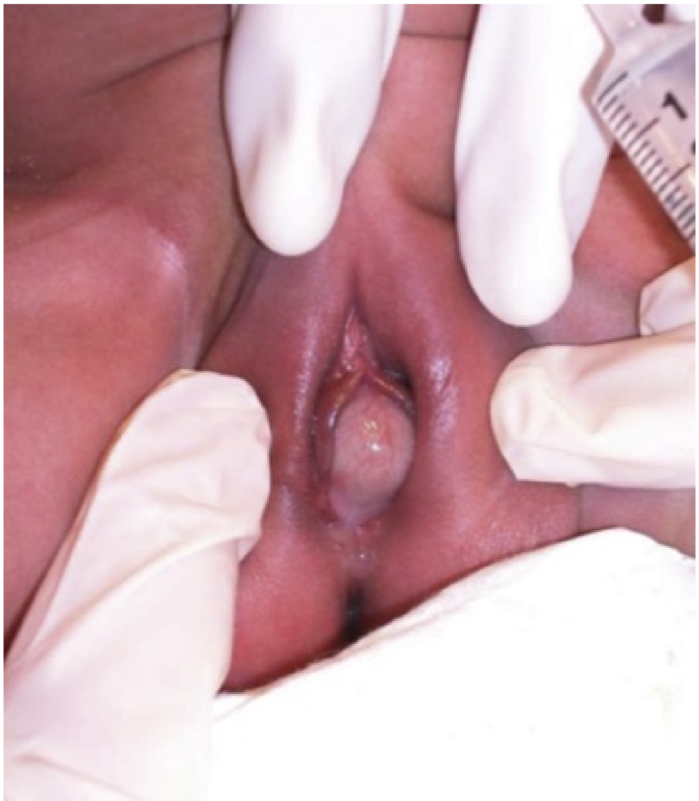

FIG. 22.28 Perineal examination reveals prolapsed ureterocele.

Exstrophy (Bladder/Cloacal)

The diagnosis of bladder/cloacal exstrophy in the prenatal period rarely gives rise for the need to therapeutically intervene. However, this does allow for appropriate identification to aid in prenatal counseling and more importantly afford the opportunity for patients to seek a center of excellence to discuss the anticipated postnatal course. The distinction between bladder and cloacal exstrophy has a profound impact on the natural history of the disease shared by caregivers and providers.

Bladder Exstrophy

Prenatally, bladder exstrophy is hallmarked by a nonvisualized bladder, abnormal genitalia, protruding mass (exstrophic bladder) inferior to a low-lying umbilicus, and widened pubic diastasis and has been reported to be detected in 50% of patients with the diagnosis (Wiesel et al., 2005) (Fig. 22.29AC). As opposed to cloacal exstrophy, the vertebral spine, kidneys, and the remainder of fetal survey is expected to be normal (Gearhart et al., 1995). Bladder exstrophy represents a midline anterior wall defect that affects the bladder and genitalia but should allow for otherwise development free from major organ system dysfunction, as seen with cloacal exstrophy. Some have reported that prenatal MRI may allow for a more complete evaluation of all organ systems to allow the condition to be definitively clarified to represent bladder exstrophy complex (Goldman et al., 2013).

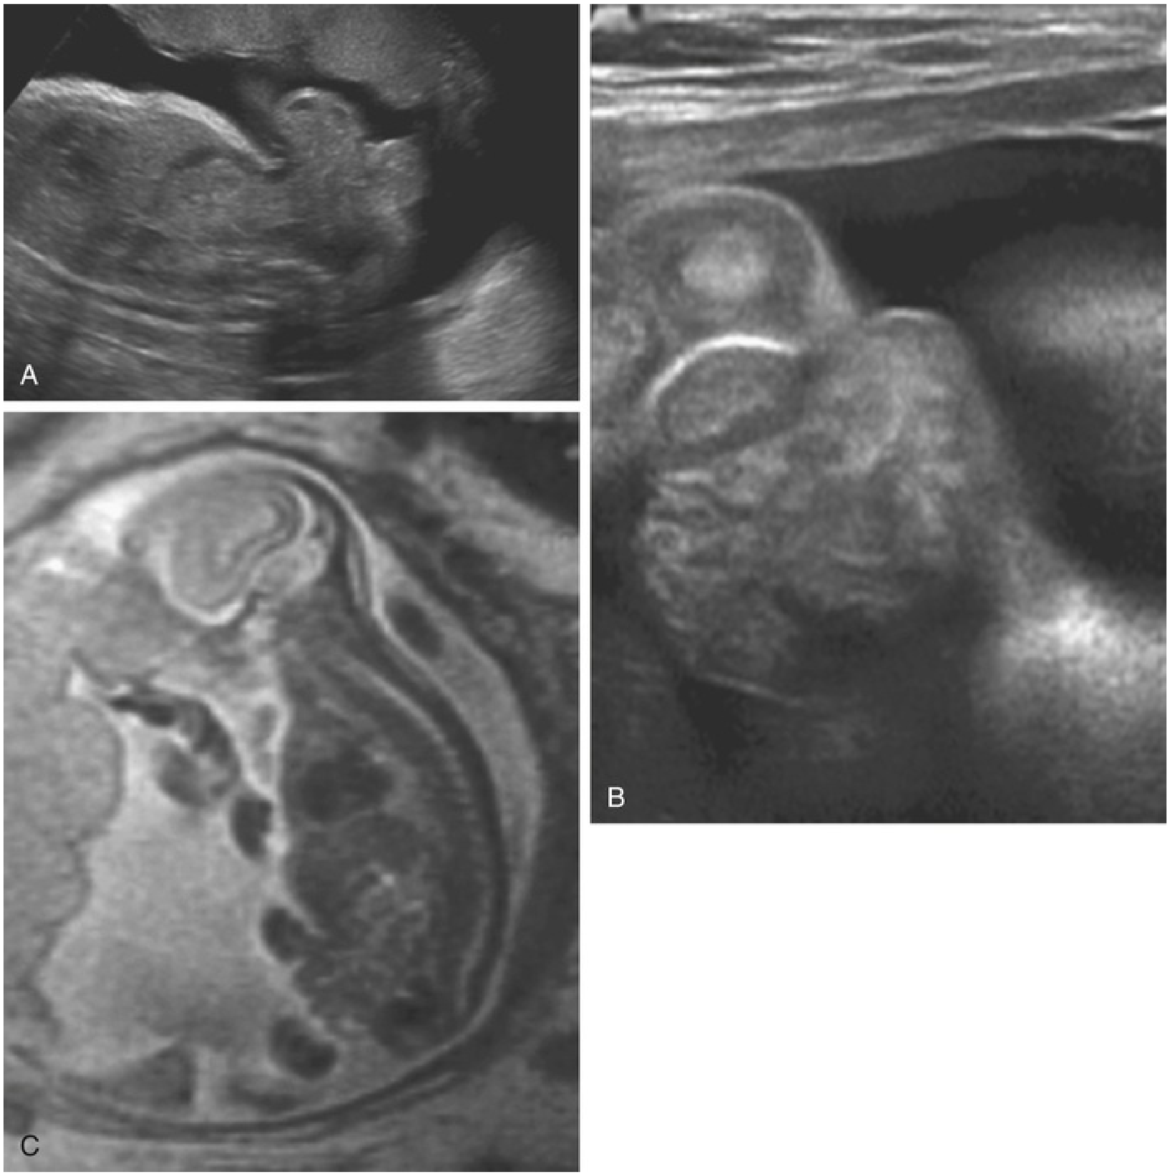

FIG. 22.29 Imaging of a male fetus with bladder exstrophy. (A) Ultrasound image in sagittal plane at 31 weeks' gestational age showing a wisp of umbilical cord, followed in caudal direction *(toward right of image)* by lower abdominal wall mass (exstrophied bladder), urethral plate, and penis. (B) Coronal view showing exstrophied bladder, penis, scrotum, and testes. (C) Sagittal magnetic resonance image showing the same fetus at 21 weeks' gestational age. Note lower abdominal wall, bladder, and penis.

Recommendations for Bladder Exstrophy

Postnatally, bladder exstrophy does not represent an emergent condition. However, the clinician should perform a thorough examination as variants of this condition such as bladder duplication may dramatically affect the expected course of this condition. Imaging should include renal ultrasonography.

Cloacal Exstrophy

The spectrum of omphalocele, exstrophy, imperforate anus, and spinal defects (OEIS) syndrome or cloacal exstrophy varies, and fortunately this condition is extremely rare. In addition to the aforementioned prenatal findings for bladder exstrophy complex, the addition of omphalocele and/or renal, vertebral, or limb anomalies may be encountered (Robin et al., 2007). **Austin et al.** (1998) **reviewed prenatal criteria for the diagnosis with a 9-patient experience that was combined with 13 historical cases in the literature. They found a persistent cloacal membrane in 3 of 22 patients and developed major and minor criteria for classifying the findings** (Table 22.5). Similar to bladder exstrophy, the early identification of cloacal exstrophy allows for prenatal counseling to occur at a center of excellence.

TABLE 22.5

Major and Minor Ultrasound Criteria for Cloacal Exstrophy

MAJOR
Nonvisualization of the urinary bladder Large midline infraumbilical anterior wall or cystic anterior wall structure (persistent cloacal membrane) Omphalocele Lumbosacral anomalies
MINOR
Lower extremity defects Renal anomalies Ascites Widened pubic arches Narrow thorax Hydrocephalus Solitary umbilical artery

Recommendations for Cloacal Bladder Exstrophy

After delivery, imaging of the patient with OEIS complex should include KUB and renal/spine ultrasonography with consideration of MRI. Decisions for surgical intervention will be dictated by the extent of organ system involvement.

Cloacal Malformation/Urogenital Sinus/Congenital Adrenal Hyperplasia

The prenatal detection of combined bladder and vaginal distention should raise the suspicion of BOO secondary to vaginal trapping of urine. The differential diagnosis should include cloacal malformation, urogenital sinus, and/or congenital adrenal hyperplasia (CAH). The latter invariably has a family history with autosomal inheritance, and the former should be associated with distal colonic obstruction, which should be seen prenatally. Prenatal counseling is a fundamental component with these conditions.

Cloacal Malformation

Cloacal malformation or persistent cloaca is rare and occurs 1 in 50,000 births. This condition only occurs in females and is a result of the arrest in development of the urorectal membrane and urogenital sinus that creates direct communication among the rectum, vagina, and urinary tract. **This condition may be associated with oligohydramnios, bilateral urinary tract dilation, and urinary ascites as seen with LUTO in males, as well as a large cystic mass arising out of the pelvis and the presence of calcified meconium caused by rectal obstruction on MRI** (Cilento et al., 1994; Hayashi et al., 2005; Shono et al., 2007; Winkler et al., 2012). One may also see a dilated vagina or uterus, and on occasion this may have a bifid character caused by a uterus didelphys. The proposed mechanism of urinary ascites is retrograde flow of urine through the uterus and fallopian tubes into the peritoneum, which may lead to oligohydramnios, but this will vary depending on the degree of gastrointestinal obstruction. Equally, an association with tracheo-esophageal fistula may be seen and should be considered in the presence of polyhydramnios. The delivery of patients with the potential diagnosis of cloacal malformation should be elective and inclusive of all necessary neonatal, pediatric surgical, and pediatric urologic care providers. The accuracy of prenatal imaging to diagnose this condition varies because of its rarity such that the clinician should have a heightened level of suspicion when the fetal ultrasound scan is suggestive of a persistent cloaca. In review of 6 patients with cloaca, Warne et al. (2002) described the Great Ormond Street experience that required fetoscopy in one patient and use of fetal MRI to diagnose the condition in two patients.

Urogenital Sinus/Congenital Adrenal Hyperplasia

CAH represents a rare autosomal recessive condition that results in a spectrum of genital ambiguity when it occurs in females. The most common variant involves 21-OH deficiency, which involves a defect in the gene that encodes 21-hydroxylase and is located on the short arm of chromosome 6. It is divided into classical, which is subdivided into salt-wasting (75%) and simple virilizing (25%) variants, and nonclassical, which has more benign course of disease. The disease afflicts 1 in 15,000 live births. The condition will clinically affect 1 of 8 in those potentially affected because males will not demonstrate ambiguity (Nimkarn et al., 2009; Winkler et al., 2012). The degree of urogenital sinus formation and genital virilization varies in severity and may be confused with other conditions such as cloacal malformation or urogenital sinus malformation.

Urogenital sinus malformation may also present with vaginal trapping of urine that leads to LUTO, similar to cloacal malformation in the absence of gastrointestinal obstruction (Fig. 22.30A–D). Urogenital sinus malformation typically has normal external genitalia, the finding of which favors the diagnosis of urogenital sinus rather than CAH.

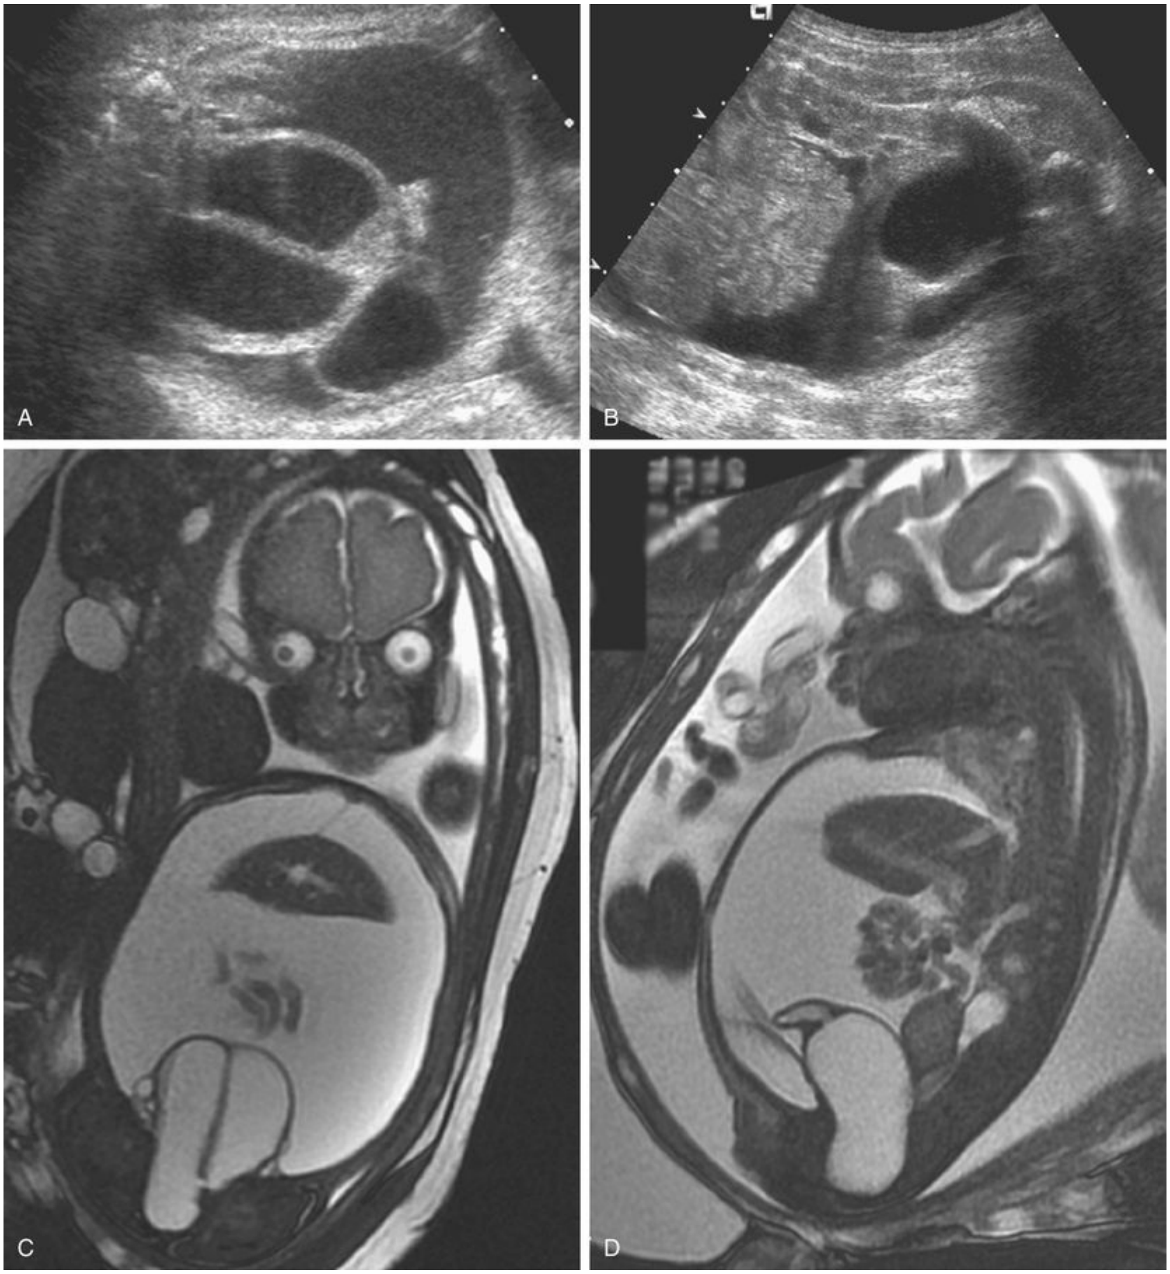

FIG. 22.30 Imaging of a female fetus at 30 weeks' gestational age with cloaca. (A) Transverse ultrasound view of abdomen showing dilated duplicate vagina, urinary bladder, and urinary ascites consistent with cloaca. (B) Sagittal ultrasound image showing bladder, markedly distended vagina, kidney with mild hydronephrosis, and urinary ascites outlining bowel and liver. (C) Coronal magnetic resonance image (MRI) showing duplicate vagina and urinary ascites. (D) Sagittal MRI of bladder, distended vagina, cervix, uterus, and intra-abdominal organs outlined by urinary ascites.

Prenatal Treatment of Congenital Adrenal Hyperplasia

Controversy exists around the prenatal identification and treatment of CAH. The condition is autosomal recessive, and with 50% of pregnancies resulting in a female birth, the overall clinical impact is 1 in 8. The partner (potential parent) with a first-degree relative or sibling with who is considering a pregnancy with a confirmed adult CAH patient should be offered genetic testing to characterize the offspring risk for disease. Fundamentally, prenatal treatment with dexamethasone administered by the 9th week of gestation is effective at reducing virilization in classical CAH in females (New et al., 2001; Nimkarn et al., 2009). This timing precedes the ability to determine fetal sex and thus exposes all children to treatment. Although prenatal treatment appears safe for the mother and fetus, the long-term impact has not been well defined and the needless exposure to 7 of 8 patients may not be justified.

Postnatal Treatment of Congenital Adrenal Hyperplasia

Postnatally, the immediate concern for electrolyte imbalance should be raised. In parallel to electrolyte stabilization, a concerted effort should be made to obtain a final diagnosis, which includes measurement of serum 17-hydroxyprogesterone and genetic testing. **Bladder decompression is a priority in those that present with LUTO secondary to vaginal retention of urine. In some cases, urinary and/or vaginal diversion will be required.** Medical and surgical care of this condition is discussed in Chapters 48 and 49.

Outcomes for Fetal Myelomeningocele Closure

The prenatal measurement of AFP combined with key ultrasound findings affords the opportunity to diagnosis neural tube defects prenatally with a high degree of accuracy **(**D'Addario et al., 2008; Boyd et al., 2008). Another biomarker that may be useful include amniotic fluid glial fibrillary acidic protein (AF-GFAP) (Lopez et al., 2013). As mentioned earlier, early prenatal diagnosis allows the ability for caregivers to consider pursuing consultation at centers of excellence that provide fetal surgical intervention.

To assess the benefit of prenatal closure of myelomeningocele, a multicenter randomized trial comparing prenatal closure versus postnatal closure was published in 2011. Prenatal closure was performed before 26 weeks' gestational age and was found to significantly decrease the need for VP shunting and appeared to improve cognitive ability and motor function as well. The most significant complications included preterm labor and uterine dehiscence (Adzick et al., 2011; Tulipan et al., 2015). **Specific to urology outcomes, prenatal closure did not improve urodynamic parameters or decrease the need for clean intermittent catheterization or urinary reconstruction** (Clayton and Brock, 2018).

Key Points

- Most patients with prenatal UTD will have transient dilation with reported resolution rates between 41% and 88%.
- Prenatal APD dilation of 15 mm in the third trimester is predictive of the need for surgery.
- VUR is reported in up to 31% of patients with prenatal UTD and occurs most commonly in males that have bilateral high-grade disease.
- MCDK does not pose an increased risk for Wilms tumor and can be safely observed in most patients.
- Duplication anomalies may be associated with VUR to the lower pole moiety, which may influence decisions for intervention to the obstructed upper pole moiety.
- Megaureter will resolve spontaneously in a majority of patients. However, surgical intervention is indicated for recurrent UTI, decreased function, or increasing UTD. Temporizing diverting procedures are recommended for patients who are younger than 1 year of age.
- Fetal closure of myelomeningocele appears to increase motor/cognitive skills and decrease the need for a VP shunt, but it does not improve urologic symptoms or urodynamic parameters or decrease the need for urinary reconstruction.

Perinatal Urgencies/Emergencies

Neonatal Urologic Emergencies

Neonatal urologic emergencies can be caused by a variety of genitourinary anomalies, birth trauma, or vascular etiologies. The urologist will often be consulted on an emergent basis for a urologic condition at birth based on clinical signs, symptoms, or physical examination. Thorough evaluation of the newborn should be pursued.

Abdominal Distension

Abdominal distension can be caused by a cystic lesion, solid mass, or urinary ascites as a consequence of obstruction or extravasation. Adjacent organs must be closely examined for concomitant involvement. A thorough examination of the entire abdomen should be performed.

Upper Urinary Tract Obstruction

Abdominal distension caused by urine collection is commonly a result of urinary tract obstruction, which is usually anticipated after detection on routine prenatal ultrasonography. The most common site of urinary tract obstruction is the UPJ. In addition to the upper tracts, urinary tract obstruction may occur at the UVJ, or the insertion site of an ectopic ureter. Percutaneous drainage may be required in select scenarios to address respiratory compromise or feeding intolerance (Fig. 22.31).

SUPINE
B

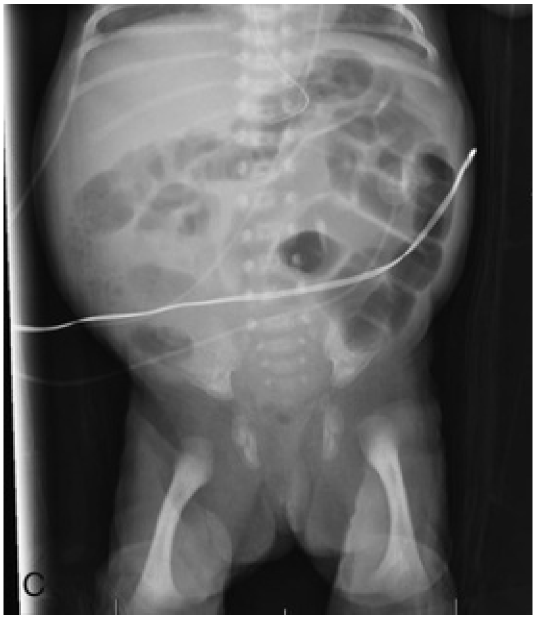

FIG. 22.31 (A) Neonatal magnetic resonance image demonstrating massive upper pole obstruction on left with ureterocele in bladder. (B) Left upper quadrant mass effect from upper pole obstruction. (C) Normalization of left upper quadrant after decompression of ureterocele.

Lower Urinary Tract Obstruction

Urinary Ascites

Urine accounts for neonatal ascites in up to 30% of cases (MacDonald et al., 1999). Neonates may display respiratory distress, oliguria/anuria, hyponatremia, hyperkalemia, and elevated serum creatinine (Oei et al., 2001). **PUV is the most common cause of urinary ascites** (Redman et al., 1979)**. Other causes of urinary ascites includes bladder rupture, cloacal malformation, persistent urogenital sinus, and urethral atresia** (Ravitz et al., 1973).

When bladder perforation is suspected, a catheter should be placed. Urine output and serum electrolytes should be followed closely. Bladder rupture can be confirmed with biochemical analysis of peritoneal fluid accompanied by a VCUG (Vasdev et al., 2009). The etiology of bladder rupture is often unexplained in the absence of obvious outlet obstruction (Vasdev et al., 2009). Most cases of spontaneous perforation heal with conservative therapy (Morrell et al., 1985). Although trauma is a rare cause of bladder perforation, there are reports of iatrogenic bladder rupture during placement of umbilical catheters that resolved with prompt recognition and surgical repair (Diamond and Ford, 1989; Dmochowski et al., 1986; Mata et al., 1987).

In a patient with persistent urogenital sinus or cloaca, urine pools in the vagina and can travel retrograde into the uterine cavity. Urinary ascites forms by urine extravasation directly into the peritoneal cavity through the fallopian tubes (Hahn-Pedersen et al., 1984). This can be diagnosed on VCUG.

Percutaneous drainage of urine may be required in select scenarios to relieve abdominal distention that affects pulmonary function.

Urinary Retention (>24 Hours After Birth)

BOO most commonly occurs in males presenting with LUTO, which may be caused by PUV, urethral atresia, or in rare occasions ureterocele. The condition will occur less commonly in females, and a high index of suspicion for urogenital sinus anomaly with vaginal distention should be considered. Equally, ureterocele may result in urinary retention as well. In addition to the aforementioned evaluation for each diagnosis, therapeutic intervention to relieve the obstruction should be pursued.

A catheter should be placed in the bladder. This may be difficult in select scenarios. For males, with PUV, a high bladder neck may impair advancement. The clinician should try placing a finger in the rectum to deflect the catheter above the bladder neck. For females, a catheter should be directed toward the bladder. However, drainage of the vagina is adequate as well and may allow for voiding.

In both scenarios, if attempts to decompress the bladder are unsuccessful, then percutaneous drainage should be pursued. **The Seldinger technique using a 16-gauge angiocatheter will allow passage of a 3.5-Fr feeding tube, or using a 14-gauge angiocatheter will allow passage of a 5-Fr feeding tube.**

In select scenarios with the urogenital sinus anomaly, intermittent drainage of the vagina will not allow bladder drainages, and a vesicostomy and/or vaginostomy may be required until definitive management can be performed (Fig. 22.32).

Solid or Cystic Renal Masses

Abdominal masses may be organized into four broad categories: renal cystic lesions, pelvic cystic lesions, solid lesions, and nongenitourinary lesions. Renal cystic lesions include MCDK, autosomal recessive polycystic kidney disease, autosomal dominant polycystic kidney disease, and cystic nephroma. MCDK will appear as a multiloculated mass with little to no renal parenchyma on postnatal ultrasonography. Bilateral evaluation is warranted as the presence of contralateral anomaly such as VUR or UPJO is common (Al-Khaldi et al., 1994; Glassberg et al., 1987).

Renal solid lesions are uncommon in newborns. The most common solid renal tumor is congenital mesoblastic nephroma (Lamb et al., 2017; Glick et al., 2004). Although most patients are diagnosed between 1 and 5 years of age, Wilms tumor can be present at birth (Homsey et al., 1997). Other causes of solid renal lesions include ossifying renal tumor, rhabdoid tumor, clear cell sarcoma, and neuroblastoma. Patients commonly present with an abdominal mass and hematuria. Paraneoplastic syndromes such as hypertension and hypercalcemia have been reported (Glick et al., 2004). **Cystic and solid lesions can be distinguished on postnatal ultrasonography along with a careful family history to detect autosomal dominant or autosomal recessive polycystic kidney disease.** Further workup is determined based on sonographic findings.

Adrenal hemorrhage may be detected on renal ultrasonography prompting urologic consultation. Adrenal hemorrhage is more common on the right side with 10% to 15% of cases presenting bilaterally (Felc, 1995; Mittelstaedt et al., 1979). Suspected causes of adrenal hemorrhage include birth trauma, hypoxia, sepsis, or coagulopathy (Velaphi and Perlman, 2001). An adrenal hemorrhage commonly appears as an echogenic mass within the adrenal gland with absence of flow on Doppler signal (Singh, 2013). **An adrenal hemorrhage can range from a small incidental finding without clinical significance to a life-threatening hemorrhage. Clinical manifestations include anemia, jaundice, hypotension, and abdominal mass** (Khuri et al., 1980)**. Scrotal hemorrhage may be present in patients with a patent processus vaginalis prompting evaluation for an acute scrotum** (Avolio et al., 2002; Duman et al., 2004). The major alternative diagnosis is neuroblastoma, which may require further evaluation with MRI. Serial **ultrasonography should be performed every 1 to 2 weeks to demonstrate decreasing size of an adrenal hemorrhage.** Over time, a resolving adrenal hemorrhage will display peripheral eggshell calcifications as opposed to the stippled appearance of neonatal neuroblastoma.

Pelvic cystic lesions can be attributable to a distended bladder or urinary ascites as discussed earlier. Another potential cause in a female patient could be hydrometrocolpos, a condition in which the vagina is distended with cervical secretions caused by vaginal atresia, transverse vaginal septum, or imperforate hymen (Hahn-Pedersen et al., 1984). Alternatively, a urogenital sinus or cloaca may result in distension of the vagina with urine (Hahn-Pedersen et al., 1984). **It is important to carefully review the imaging as hydrometrocolpos can be mistaken for a distended bladder.** Ovarian cysts are common, occurring in up to 30% of female neonates (Bryant and Laufer, 2004). The characteristic ultrasound appearance is an anechoic, unilocular mass in the fetal pelvis (Meizner et al., 1991). Most ovarian cysts resolve spontaneously in the first 6 months of life (Bagolan et al., 2002).

Anorectal Malformation

The urologist should suspect genitourinary and spinal anomalies in any patient who presents with anorectal malformation as the incidence can approach 75% (McLorie et al., 1987). The most common anomalies include VUR, renal dysplasia, renal agenesis, and cryptorchidism (McLorie et al., 1987). The initial workup should include a thorough inspection of the perineum and back, and ultrasonography. The neonate should undergo spinal ultrasonography in the newborn period to rule out a tethered cord. **Assessment for VUR can be combined with videourodynamics and performed at 6 weeks of age. The patient should be maintained on urinary prophylaxis until this is performed.**

Ambiguous Genitalia

The urologist may be consulted emergently to examine a neonate born with ambiguous genitalia. This type of consultation can cause severe parental anxiety, and care should be taken to address parental concerns with sensitivity. **It is important to involve a multidisciplinary team of clinicians who are well-versed in disorders of sexual differentiation such as an endocrinologist, psychiatrist, and geneticist. The medical team should focus on correct diagnosis of the condition and gender assignment and should counsel the family appropriately on relevant management** (Lambert et al., 2010).

The most common cause of ambiguous genitalia at birth is CAH, which can affect up to 1 in 16,000 births (Speiser and White, 2003). Of babies born with ambiguous genitalia, 46,XX disorder of sex development (DSD) is the most common and results from exposure to androgens in fetal life caused by enzyme deficiency in the testosterone pathway or maternal exposure to androgens. Physical examination will not demonstrate palpable gonads. Ultrasonography will reveal a uterus and ovaries.

Initial evaluation should focus on the identification of classical salt-wasting CAH in which aldosterone synthesis is disrupted. An elevated serum potassium and low serum sodium level can lead to dehydration and cardiac arrhythmias. Laboratory testing should include karyotyping and serum studies including electrolytes, 17-hydroxyprogesterone, testosterone, and dihydrotestosterone levels. Other less common diagnoses that may account for ambiguous genitalia at birth include 46,XY DSD, 46,XX testicular DSD, sex chromosome DSD, and ovotesticular DSD. Accurate diagnosis of these conditions may require gonadal biopsy (discussed in detail in Chapter 48).

Intralabial Masses in a Female Patient

A clinician who is consulted to examine a newborn female with an interlabial mass should consider four main diagnoses: **imperforate hymen, prolapsed urethra, prolapsed ureterocele, and paraurethral cyst.** The diagnosis is often confirmed on physical examination. Gentle probing of the mass with a cotton-tipped applicator will assist in elucidating perineal anatomy. **An imperforate hymen or prolapsed urethra will appear in the midline. Hydrometrocolpos caused by imperforate hymen will appear as a white, bulging membrane at the introitus with or without associated UTD** (Turner and Leonard, 1997). Sonography will demonstrate fluid collection behind the bladder. Treatment involves incision of the hymen to allow the milky white secretions to drain from the vagina. **Urethral prolapse is uncommon in the newborn period. It appears as a circumferential collar of edematous and ecchymotic tissue at the urethral meatus and is more common in African-American females** (Lowe et al., 1986). Symptomatic treatment with warm compresses, topical moisturizers, and prevention of straining and coughing is advised.

Interlabial masses that typically do not appear in the midline include prolapsed ureterocele and paraurethral cyst. In both cases, an intact hymenal ring will be identified posterior to the lesion. A prolapsed ureterocele appears as a cystic structure emanating from the urethral meatus. Confirmation is achieved with ultrasonography and VCUG. A parameatal cyst is an opalescent, ovoid structure that will sometimes displace the urethral meatus and may interfere with urinary stream. Most parameatal cysts resolve without intervention (Herek et al., 2000).

Oliguria/Anuria

Most healthy neonates will void within the first 24 hours of life (Vuohelainen et al., 2008)**. Delay beyond the first day of life is generally benign but may result in parental anxiety. On examination, gentle palpation of the suprapubic region may prompt the neonate to void.** Ultrasound examination may be performed to visualize a distended bladder. Healthy males will void in a predictable pattern following circumcision. Seventy-five percent of breastfed males and 100% of formula-fed infants will void within 8 hours following circumcision (Narchi and Kulaylat, 1998).

Gross Hematuria

The urologic consultation for neonatal gross hematuria has a wide differential diagnosis (Table 22.6**). Urinalysis with microscopy should be performed to confirm that the blood is urinary in origin.** In female neonates, blood on the diaper is caused by withdrawal from maternal estrogens and will resolve spontaneously without intervention. Furthermore, blood on the diaper from dermatitis after a circumcision or red staining of urate crystals may be falsely attributed to hematuria.

TABLE 22.6

RENAL
• Renal cortical/papillary necrosis • Glomerulonephritis

PKD, Polycystic kidney disease; *PUV,* posterior urethral valve; *UPJO,* ureteropelvic junction obstruction.

Initial workup should include abdominal ultrasonography with Doppler to evaluate the vasculature. The presence of hypertension in a neonate with gross hematuria suggests greater severity of disease. The clinician should suspect a thrombotic event, polycystic kidney disease, or renal cortical necrosis. **The most common thrombotic event is renal vein thrombosis (RVT), which accounts for up to 20% of cases of gross hematuria. RVT may present with the classic triad of gross hematuria, flank mass, and thrombocytopenia. Risk factors include maternal diabetes, prematurity, umbilical venous catheterization, and polycythemia.** Up to 50% of neonates with RVT have a prothrombotic disorder and should undergo hematologic evaluation (Kuhle et al., 2004). **Treatment consists of aggressive hydration and expectant management. Anticoagulation should be considered, and consultation with pediatric nephrology should be obtained.**

Renal artery thrombosis (RAT) is chiefly caused by umbilical artery catheter placement. The clinical presentation includes hypertension and congestive heart failure. A renal scan may reveal lack of perfusion to areas of the cortex. The umbilical artery catheter should be removed and thrombolytic therapy may be initiated (Schmidt and Andrew, 1995).

Renal cortical necrosis can result from any condition in which perfusion to the kidneys is decreased. Risk factors include hypotension, anoxia, severe hemorrhage, necrotizing enterocolitis, sepsis, placental abruption, or twin-twin transfusion syndrome (Jernigan, 2014). Renal ultrasonography will demonstrate loss of corticomedullary differentiation with a hypoechoic rim at the edge of the renal cortex (Sefczek et al., 1984). Treatment is supportive. Neonates who experience renal cortical necrosis carry a lifetime risk for renal failure.

Scrotal Mass in the Neonate

The assessment of a newborn scrotal mass should discern the acuity of the condition. A thorough discussion with the nursing staff and delivery team combined with palpation should allow for this assessment. The differential diagnosis is listed in Table 22.7.

TABLE 22.7

Causes of Scrotal Masses in the Neonate

Extravaginal torsion
Appendage torsion
Incarcerated hernia
Hydrocele
Epididymal cyst
Meconium
Testis tumors
Trauma
Hematoma from adrenal hemorrhage
Tumor seeding (renal or adrenal tumors)

Testicular Torsion

Testicular torsion in the newborn may be time-sensitive depending on the acuity of the presentation. Typically, torsion in the newborn period is extravaginal, which involves twisting of the tunica vaginalis and the spermatic cord contained within. Extravaginal torsion may be categorized into two separate phenomena, prenatal torsion (in utero) and postnatal torsion (acute) (during the first 30 days of life). This distinction is important because the salvage rate of a prenatally torsed testis is nearly nonexistent, whereas a postnatal extravaginal torsion carries a salvage rate of up to 44% (Brandt et al., 1992; Sorensen et al., 2003). Indeed, a survey of pediatric urologists found that 43% of respondents would treat a prenatal torsion as a surgical emergency, whereas 93% would immediately explore a neonate with postnatal torsion (Broderick et al., 2013).

A neonate with prenatal testicular torsion will present with an enlarged discolored scrotum accompanied by a nontender, solid testis that is fixed to the scrotal wall. In contrast, postnatal torsion will present with a postnatal change in scrotal examination (erythema and/or swelling), and the testis will be tender. In prenatal torsion, the testis will likely appear hyperechoic and avascular. In both prenatal and postnatal torsion, the testis can appear heterogeneous in echotexture. Bilateral or unilateral hydrocele may be present. Doppler studies will demonstrate absence of flow in the affected testis (Arena et al., 2006).

In the case of a nonsalvageable prenatal torsion, a contralateral orchidopexy may be performed on an urgent basis to avoid the devastating consequence of asynchronous contralateral torsion. There is no uniform agreement among pediatric urologists in regard to the urgency or ultimate need to explore these children. Generally, the risk for extravaginal torsion is thought to be present for only the first few weeks of life, and intervention should be pursued before this window closes.

For postnatal testicular torsion, management should be similar to what is recommended for acute testicular torsion that appears later in life, recognizing that the timing of presentation varies. The decision to proceed with immediate surgical exploration should be measured in which the parents are aware of the low salvage rate for the affected testis (Brandt et al., 1992; Sorenson et al., 2003). The main rationale behind intervention for postnatal torsion is the prevention of asynchronous contralateral torsion. A spinal anesthetic can be employed to avoid neonatal exposure to inhalation anesthetic.

To identify a scrotal mass, a thorough physical examination should be undertaken. Transillumination can assist in identifying a hydrocele. Gentle palpation of the mass may unveil a reducible inguinal hernia or a communicating hydrocele. An abdominal radiograph may reveal bowel gas in the scrotum if herniated bowel is present. The presence of stippled calcifications suggests a history of meconium peritonitis (Kenney et al., 1985). Wilms tumor or neuroblastoma may seed the testis through a patent processus. Scrotal hematoma has been reported to masquerade as neonatal torsion (Diamond, 2003). Testis tumors in this age group are rare and include yolk sac tumors, teratomas, juvenile granulosa cell tumors, and gonadal stromal tumors (Levy et al., 1994). Although rare, it is important to include possible malignancy in the differential diagnosis of a scrotal mass and perform an abdominal ultrasonography when suspected.

Key Points

- A urologic source for abdominal distention in the newborn includes urinary ascites, urinary obstruction (upper and lower tract), renal mass (cystic and solid), and rarely a retroperitoneal mass (adrenal).
- Urinary retention may occur with LUTO and may occur in males with PUV or females with urogenital sinus or cloacal anomaly.
- Renal tumors are uncommon in the newborn period, and the most common is mesoblastic nephroma.
- The newborn with ambiguous genitalia should prompt an evaluation for electrolyte disturbance caused by classical salt-wasting CAH. Gender assignment should be deferred.
- Gross hematuria in the neonate is not common and should be evaluated with urine analysis and Doppler abdominal ultrasonography.
- The acuity of neonatal testicular torsion will dictate the need for emergent exploration.

Urologic Evaluation of the Child

Rachel Selekman MD, MAS, Hillary L. Copp MD, MS

Overview of Pediatric Urology

Pediatric urologists provide complete urologic care for children, performing not only the initial evaluation and diagnosis but also the medical and surgical therapy for diseases of the genitourinary system. Pediatric urology encompasses a spectrum of congenital and acquired disorders ranging from complex congenital anomalies such as bladder exstrophy to more routine, but nevertheless important, problems such as daytime wetting in a school-aged child. The basic approach to the pediatric patient requires taking a complete history, executing a thorough physical examination, and obtaining appropriate imaging as indicated.

In most cases, the pediatric urologist's initial contact with the patient is through an outpatient referral from a primary care physician or obstetrician seeking prenatal evaluation. However, some patients are seen in the emergency room or urgent care, and immediate consultation is requested. The pediatric urologist must efficiently assess patients and triage those requiring urgent evaluation versus those who are best cared for nonacutely by referral to the office setting (Table 23.1).

TABLE 23.1

Triage of Common Urologic Consults

Emergent	Acute postoperative problem
	Acute scrotum
	Newborn with ambiguous genitalia, bladder or cloacal exstrophy, posterior urethral valves, prune-belly syndrome, spina bifida
	Paraphimosis
	Priapism
	Trauma
Urgent (within 24 hours)	Newborn with bilateral hydronephrosis or solitary kidney with hydronephrosis
	Renal tumor
	Testicular mass
Semi-urgent (within 1–3 weeks)	Afebrile nephrolithiasis
	Amenorrhea in an adolescent female
	Consultation after treatment of a febrile urinary tract infection
	Gross hematuria in the absence of infection
	Interlabial mass

	Postnatal evaluation of prenatal unilateral hydronephrosis
Routine (at the family's convenience)	Asymptomatic hernia or hydrocele
	Circumcision evaluation
	Enuresis
	Hypospadias
	Labial adhesions
	Microscopic hematuria
	Undescended testicle
	Varicocele

This chapter introduces the pediatric urologic evaluation, focusing on the history and physical examination with emphasis on common clinical entities, examination techniques, and adjunct investigations such as radiographic imaging and select laboratory testing that are relevant to pediatric patients. The management of a pediatric patient with a urologic problem is often complex. The reader may find further details about specific conditions in other chapters.

Imaging

Radiologic evaluation of the pediatric patient initially consisted of abdominal plain films, then intravenous urography and voiding cystourethrography were introduced (Riccabona et al., 2002). Over the past decades, these modalities have undergone many developments and refinements. Then ultrasound was introduced to diagnostic imaging followed by nuclear medicine investigations. The need to reduce radiation exposure to the at-risk pediatric population and the increasing demand to combine morphologic and functional studies have driven innovations in these modalities as well as in computed tomography (CT) and magnetic resonance urography (MRU) (Darge et al., 2010). The following discussion focuses on the most common imaging modalities in modern pediatric urology with an overview of state-of-the-art techniques.

Ultrasonography

Ultrasonography is fundamental to pediatric urology. It is a relatively inexpensive imaging modality providing real-time evaluation of urologic structures without the need for sedation, ionizing radiation, or contrast agent injection. It is generally used as the primary imaging tool allowing for screening, providing orienting information to direct further imaging strategy, and allows for repeated follow-up investigations for monitoring the course of a urologic condition.

Renal Bladder Ultrasound

A pediatric renal bladder ultrasound requires an ultrasound device technically suited to neonatal, infant, or child with a variety of transducers with adaptable frequencies (3–10 MHz) (Riccabona et al., 2002). The patient must be hydrated with a full urinary bladder. A thorough ultrasound of the urogenital tract consists of evaluation of the bladder in longitudinal and transverse as well as oblique sections with visualization of the bladder wall, the ostial area, the distal ureters, the bladder neck, and the proximal urethra (partially using a transperineal approach), in the initially full bladder. Bladder capacity is measured. Kidneys are evaluated from ventral, lateral, and dorsal approaches, using prone and supine positioning, in multiple longitudinal and transverse sections covering the entire organ, also using high-resolution linear transducers for evaluation of renal parenchyma (including for corticomedullary differentiation, degree of echogenicity, and presence of cysts) noting renal volume measurements. Assessment of the renal collecting system is achieved with standardized axial measurement of any calyceal or pelvic distention, in prone and supine positions. Measurement of the ureters, if visible, should be performed. Last, the clinician should perform a postvoid evaluation, noting any residual urine in the bladder as well as reevaluating the distal ureters and the renal collecting system.

Advanced ultrasound techniques have significantly improved the potential of ultrasonography, particularly in evaluation of vesicoureteral reflux (VUR) and renal perfusion disturbances such as segmental pyelonephritis. New applications with particular importance in pediatric sonography are summarized here (Riccabona, 2009).

1. M-mode enables semi-quantitative assessment of ureteric peristalsis.
2. Harmonic imaging improves border delineation, particularly in liquid-filled structures such as the dilated collecting system, reduces artifacts, and improves depiction of ultrasound contrast media.
3. Sonographic contrast medium instilled into the bladder via a catheter enables a sonographic assessment of VUR and genitography without radiation exposure.
4. Doppler techniques allow a semiquantitative assessment of renal blood flow and perfusion. Color Doppler sonography gives a quick and comprehensive overview of vessel anatomy as well as flow velocity and direction in the renal vessels. The twinkling sign has improved potential for the assessment of urolithiasis, and color Doppler sonography improves assessment of the ureteric inflow jet.
5. Duplex Doppler sonography provides detailed information of flow profiles with a physiologically lower flow velocity, a higher resistive index, and relatively lower diastolic flow velocity evaluating indirect signs for perfusion disturbances (e.g., in renal vein thrombosis, renal artery stenosis, or renal failure).
6. Amplitude-coded color Doppler sonography demonstrates blood flow volume and allows depiction of peripheral renal vasculature and diagnosis of impaired perfusion.

However, ultrasonography has limitations not yet overcome by advanced techniques. Conventional ultrasonography is poor in detecting VUR and in anatomic evaluation of the urethra and the ureter. However, indirect signs such as thickening of the ureteric and pelvic wall, calyceal distention, renal parenchymal disease, dilated ureters, bladder wall thickening and trabeculation, or residual volume after voiding may indicate these pathologies. **Ultrasonography remains equipment and operator dependent and offers little functional information in the urinary bladder and insufficient anatomic evaluation of the ureters and urethra. Furthermore, it cannot distinguish obstructive from nonobstructive hydronephrosis. Therefore it is often used in conjunction with other imaging modalities.**

Prenatal Ultrasonography

The use of prenatal ultrasonography has increased globally, driven by enhancement of clinical care, improvement in technology access, changes in health care policy, financial interest, medicolegal fear, and necessity for parental reassurance (Clayton and Brock, 2011). Genitourinary anomalies are among the most commonly detected findings. In a large study of nearly 3700 fetuses with structural malformations, genitourinary anomalies composed approximately 20% of all structural malformations, with an increased sensitivity in the second trimester of 89% (Grandjean et al., 1999). Hydronephrosis is the most frequently identified fetal urologic abnormality, but the severity and clinical implications of prenatal hydronephrosis can vary greatly. The majority of fetuses with a urologic anomaly can be managed expectantly; those with suspected lower urinary tract obstruction may need urgent pediatric urology consultation (Clayton and Brock, 2012).

Scrotal Ultrasonography

Advances in ultrasound technology in recent years have made ultrasound the examination of choice for imaging scrotal pathology, whether acute or chronic (Munden and Trautwein, 2000). In addition, **Doppler technology has tremendously increased the radiologist's ability to assess flow within the prepubertal testicle if spermatic cord torsion is suspected**. Color Doppler sonography allows simultaneous real-time display of tissue morphology in gray-scale and color-encoded characteristics of blood flow**. It has a diagnostic accuracy of 95% in testicular torsion, similar to that obtained with radionuclide testicular scanning** (Pepe et al., 2006). Notably, ultrasonography should not be used in the evaluation of cryptorchidism. **It does not reliably localize nonpalpable testes nor rule out an intraabdominal testis; thus it does not assist in decision making** (Tasian and Copp, 2011).

Occult Spinal Dysraphism

The prevalence of occult spinal dysraphism is increased in children with urogenital anomalies (Koo et al., 2012). Spinal ultrasound has become more widely used for the evaluation of spinal lesions. It can be used in infants before 6 months of age when ossification of posterior elements prevents an acoustic window (Hughes et al., 2003). At this age, it has good agreement with magnetic resonance imaging (MRI), particularly for the detection of low-lying cord (90%). Because ossification timing is variable, it is recommended not to delay evaluation of concerning spinal lesions with spinal ultrasound.

Voiding Cystourethrogram

A voiding cystourethrogram is a classic, established examination in pediatric uroradiology. It may be performed either with fluoroscopy and iodinated contrast medium or with nuclear imaging agents (usually technetium-99m [^{99m}Tc] pertechnetate) using similar techniques.

Fluoroscopy

The examination begins with an initial plain film. This film should be inspected for bony abnormalities, the presence of stones, and the volume of stool. The bladder is catheterized, emptied, and low-pressure infusion of the radio-opaque contrast using physiologic filling pressures is begun (Riccabona, 2002). **During filling, oblique views of the ostial area should be obtained, particularly for demonstration of the anatomy of the vesicoureteral junction (e.g., ureteroceles or diverticula). Lateral views demonstrate low-degree VUR as well as the anatomy of the male urethra to assess for posterior urethral valves. In refluxing units, the kidney must be evaluated for the degree of calyceal distention, potential intrarenal reflux, and anatomic variations (e.g., duplex systems). The urethra and bladder must be visualized during voiding with attention to the bladder neck.** The presence of a widened proximal urethra, “spinning top urethra,” may be an important indicator of dysfunctional voiding (Saxton et al., 1988). Last, postvoid evaluation should include assessment of drainage of refluxed material from the upper collecting system, presence of any residual material in the bladder, and vaginal voiding in girls. Cyclic filling enables a higher vesicoureteral reflux detection rate (Hellstrom and Jacobsson, 1999; Polito et al., 2000).

Nuclear Cystography

The radionuclide voiding cystourethrogram may be more sensitive for reflux detection but offers poorer spatial resolution so that details of the urethra and collecting system and degree of reflux may not be seen (Darge and Riedmiller, 2004). The main advantage of radionuclide voiding cystourethrogram has been the lower radiation exposure compared with a fluoroscopic voiding cystourethrogram. However, modern imaging technology and a tailored examination has decreased the radiation exposure of the fluoroscopic voiding cystourethrogram (Haid et al., 2015).

Genitography

The anatomic evaluation of patients with complex congenital disorders may be useful to define anatomy for surgical reconstruction. This is commonly performed with a genitogram by placing catheters within sinuses and filling the entire bladder, urethra, vagina, and sinus(es) with contrast (al Jurayyan et al., 1995). It is important to identify a cervical impression at the vaginal dome, which suggests normal female internal organs. Notably, magnetic resonance imaging may also aid in defining the anatomy in pure urogenital sinus anomalies or patients with disorders of sex development.

Renal Scintigraphy

Radionuclide renal scintigraphy provides functional data to assist in the diagnosis and management of patients with a variety of suspected genitourinary tract problems, including obstruction (diuresis renography) and pyelonephritis and/or renal scar (renal cortical scintigraphy) (Taylor, 2014).

Diuretic Renography

Diuretic renography is based on a high endogenous rate of urine flow stimulated by the administration of furosemide; interpretation is based on washout of the radiopharmaceutical from the collecting system of the upper urinary tract (Taylor, 2014). The patient must be well hydrated and have an empty urinary bladder before the examination because a full bladder may affect upper-tract emptying and give false-positive results. The Paediatric Committee of the European Association of Nuclear Medicine has proposed guidelines for renograms in children and recommend tubular agents such as ^{99m}Tc-mercaptoacetyltriglycine for diuresis renography because tubular tracers are much more efficiently extracted by the kidney (Gordon et al., 2011).

Renography allows estimation of two aspects of renal function. First, renal clearance is the extraction of the tracer from the blood. This allows for the estimation of differential renal function by relative clearance and is undertaken 1 to 2 minutes after tracer injection. Second, renal excretion is the disappearance of the tracer from the kidney. This allows for evaluation of obstruction. Disappearance can be estimated by inspecting the renogram curve: an early peak followed by a rapidly descending phase is typical for normal excretion. A delay in excretion is characterized by a continuously ascending curve over 20 min or a curve that fails to fall and appears as a plateau.

Renal Cortical Scintigraphy

Renal cortical ^{99m}Tc-dimercaptosuccinic acid scintigraphy demonstrates a homogeneous concentration of the radiotracer throughout the kidney except for a lower concentration in the region of the collecting system (Taylor, 2014). They provide identification of functioning renal tissue in patients with congenital abnormalities or nonstandard anatomic location of the kidneys. These scans are also used to detect cortical abnormalities related to urinary tract infection (UTI) with a higher sensitivity in acute and chronic pyelonephritis compared with ultrasonography (Piepsz et al., 2001). Pyelonephritis and scarring are recognized by focal areas of decreased ^{99m}Tc-dimercaptosuccinic uptake in the renal parenchyma; however, a focal abnormality is not specific for pyelonephritis or a renal scar because any process that replaces, injures, or destroys normal cortical parenchyma will result in an abnormal scan. In addition, they measure relative function.

Urodynamic Testing

Urodynamic studies have become common practice in the evaluation of infants and children with neurogenic or nonneurogenic bladder given its

ability to provide an accurate assessment of lower urinary tract function for diagnosis and monitoring of response to treatment (Drzewiecki and Bauer, 2011)**. Urodynamic testing assesses bladder capacity, contractility, compliance, emptying ability, and degree of continence.** Urethral and rectal catheters are used to obtain intravesical and intra-abdominal pressure recordings. Detrusor pressure is calculated by continuous subtraction of the intra-abdominal from the intravesical pressure to correct for changes that may occur during laughing, coughing, movement, or talking during the study.

After the child voids or is catheterized (if maintained on clean intermittent catheterization), a multi-lumen urodynamic catheter is placed. The postvoid or postcatheter residual is measured. The child is made comfortable in the supine or sitting position. Electromyography of the external sphincter is performed by placing patch electromyography electrodes on the perineum. A rectal urodynamic catheter is placed to measure abdominal pressure. The bladder is then filled to expected bladder capacity at a rate 5% to 10% of the expected capacity per minute with warmed saline. Filling should continue until the child has a strong urge to void or is uncomfortable, micturition occurs, detrusor pressure exceeds 40 cm H_2O, infused fluid volume exceeds 150% of expected capacity, or the rate of leakage is greater than the rate of infusion. The filling cycle should be repeated to ensure accuracy. If available, the addition of fluoroscopic video imaging reveals the overall shape and contour of the bladder and bladder neck during filling and voiding and can identify intrinsic sphincter deficiency. Children are then encouraged to void, if able, with assessment of voiding pressure and electromyogram tracings.

Advanced Imaging

Magnetic Resonance Imaging

A comprehensive MR urography (MRU) protocol is a two-part imaging technique composed of precontrast sequences (static MRU) and postcontrast sequences (dynamic or excretory MRU) (Renjen et al., 2012). Magnetic resonance imaging (MRI) provides noninvasive cross-sectional imaging with excellent definition of normal anatomy, anomalous development, and pathological processes (Nguyen et al., 2006). Uniquely, MRI can also give functional information on the kidney (Hiorns, 2010). It can be used to evaluate congenital anomalies, mainly pelvicaliectasis and/or ureterectasis, and renal and bladder tumors. In addition, it provides additional anatomic detail when antenatal ultrasonography is inconclusive (Kajbafzadeh et al., 2008).

MRI is performed without exposure to ionizing radiation. However, the widespread use of MRI in pediatric uroradiology is limited by the requirement for sedation in young children, the lack of widely available MRI technology, and the high cost of MRI (Darge et al., 2013). Sedation can be avoided in infants, primarily those younger than 3 months of age, with the feed-and-wrap technique, which uses feeding and swaddling to induce natural sleep (Antonov et al., 2017).

Computed Tomography

Computed tomography (CT), with and without contrast enhancement, has become the mainstay of uroradiology in adults. It has been an attractive modality in children not because of diagnostic yield, but because of its availability, speed, lack of need for sedation, and cost efficacy (Hiorns, 2010). **However, its use in children is limited. There is a relatively high radiation dose required.** In addition, children have an increased sensitivity to radiation not only because of their long expected lifespan from the time of radiation exposure but also because of their growing status, as dividing cells are at increased risk for damage (Khong et al., 2013). In addition, infants have less fat (which changes the absorption of radiation serving as natural contrast), smaller structures, and different diseases (less malignancy and nephrolithiasis), further limiting the benefit of CT (Riccabona, 2009). **At present, CT should be used in pediatric urology in the context of severe blunt abdominal trauma and polytrauma, in stone disease, and for CT-angiography for evaluation of renal arteries** (Darge et al., 2013). Although ultrasonography should be used for initial diagnostic imaging in children with suspected nephrolithiasis, CT should be used for those with a nondiagnostic ultrasound in whom the clinical suspicion for stones remains high (Tasian and Copelovitch, 2014). Furthermore, radiation dose may be reduced by employing ultra-low-dose or low-dose protocols, which yield high sensitivity and specificity in evaluating renal colic, although may not be as effective in detecting stones smaller than 3 mm or in patients with a body mass index of more than 30 kg/m^2 (Rob et al., 2017).

If CT is indicated, dedicated age- and weight-adapted pediatric protocols for contrast medium and exposure parameters together with properly adjusted timing should be used. The scan area and range should be kept as small as possible and restricted to the clinically necessary size, and multiphasic scans should be avoided.

Key Points

- Ultrasonography is fundamental to pediatric urology. It is inexpensive and does not require sedation or radiation. It is used as the primary imaging tool.
- A voiding cystourethrogram is performed with fluoroscopy or nuclear imaging and evaluates for vesicoureteral reflux and posterior urethral valves.
- Radionuclide renal scintigraphy provides functional data for the diagnosis and management of obstruction, pyelonephritis, and renal scar.
- Urodynamic studies evaluate bladder function by assessing bladder capacity, contractility, compliance, emptying, and continence.
- MR urography provides anatomic detail and functional information without radiation, but its use is limited by availability, cost, and the need for sedation in some.

Presentations by Genitourinary Region

External Genitalia of the Male

Scrotal Conditions

Undescended Testicle.

Boys with an empty hemiscrotum at birth concerning for an undescended testis, also known as cryptorchidism, are among the most common referrals to the pediatric urologist. An empty hemiscrotum at birth represents either in utero torsion of the testicle or cryptorchidism. The incidence of congenital cryptorchidism in full-term boys is estimated to be 2% to 4% at birth and 1% at 1 year of age with increased incidence associated with prematurity and low birth weight (Barthold and Gonzalez, 2003; Weidner et al., 1999)**. In addition, older boys may develop acquired cryptorchidism because of ascending testes** (Gracia et al., 1997)**. Surgical correction is recommended for cryptorchidism, and the operative approach is based on the palpability and location of the testis; thus a careful physical exam is critical. Importantly, ultrasound does not reliably localize nonpalpable testicles nor does it rule out intraabdominal testicles and thus has no role in the routine evaluation of a child with an empty hemiscrotum** (Tasian and Copp, 2011).

There are multiple ways to examine a patient for cryptorchidism, and the examiner should use the method that is successful for him or her. As demonstrated in Video 23.1▶, we prefer to examine the patient in a warm room in supine position with legs spread apart, although frog-legged or standing positions are also common positions for successful examination. The inguinal canal should be visually inspected for signs of asymmetry or mass. An examiner stands on the side contralateral to the empty hemiscrotum and closes the internal inguinal ring with his or her nondominant hand to prevent a testicle from migrating into the abdomen. The examiner then slides his or her dominant hand from the anterior superior iliac spine down to the pubic tubercle to feel a testicle within the inguinal canal. To aid in lubrication, we recommend using a glove lubricated with soap and water. It is important to determine size, location, and texture of both gonads, with consideration of the anatomy of the testis, the epididymis, and the vas deferens, if palpable. The undescended testis may be found in the inguinal canal; in the superficial inguinal pouch; at the upper scrotum; or, rarely, in the femoral, perineal, or contralateral scrotal regions. If the testicle can be easily pulled into the scrotum and remains there upon release, it is a retractile testicle and needs no additional therapy. If the testicle is palpable but will not descend, it will require surgical correction. If doubt exists, a repeat examination 6 to 18 months later may be diagnostic as an ascended testicle becomes more difficult to manipulate into the scrotum as the boy ages. If the testicle is nonpalpable it may be intraabdominal or not present (from in utero testicular torsion). In this setting operative exploration is indicated. **Last, if gonads are nonpalpable bilaterally, a thorough examination for a disorder of sexual differentiation is indicated.**

Scrotal and Testicular Pain.

Acute scrotal pain is one of the most common urologic complaints seen in pediatric emergency departments. Boys with many types of inguinoscrotal pathology may have acute scrotal pain or swelling. **When findings are suspicious for spermatic cord torsion, emergent scrotal exploration is required with the goal of the patient getting to the operating room within 4 hours of onset of pain.** Thus obtaining a thorough history and physical exam is critically important to appropriately treat boys with spermatic cord torsion and to avoid unnecessary surgery in those who do not.

The differential diagnosis of acute scrotal pain includes spermatic cord torsion, torsion of the appendix testis or appendix epididymis, epididymitis/orchitis, hernia/hydrocele, trauma, sexual abuse, tumor, idiopathic scrotal edema, dermatitis, cellulitis, and vasculitis (Gatti and Patrick Murphy, 2007). Evaluation should begin with a history obtained from the caretaker and the patient. The examiner should inquire regarding the onset of pain because gradual onset of scrotal pain is more consistent with epididymitis, whereas sudden onset of scrotal pain suggests torsion of the spermatic cord or one of the appendices. Associated symptoms such as nausea and vomiting should be investigated because these are also more consistent with torsion of the spermatic cord or one of the appendices. Finally, a physical examination should be performed. Associated scrotal wall swelling, erythema, and superior displacement of the testis with an absent cremasteric reflex are very suggestive of spermatic cord torsion. However, the absence of any of these findings does not rule out torsion.

Testicular Torsion.

Two types of testicular torsion may occur: extravaginal torsion resulting from twisting of the spermatic cord proximal to the tunica vaginalis and intravaginal torsion resulting from the testicle and epididymis twisting within the tunica vaginalis. Extravaginal torsion occurs perinatally, whereas intravaginal torsion may occur at any time, with peak frequency during early adolescence (Skoglund et al., 1970; Zhao et al., 2011).

Management of perinatal extravaginal torsion remains controversial with varied opinions regarding the merit and role of "emergent" testicular exploration given the very low salvage rate as well as the role of contralateral orchidopexy of the healthy testis (Snyder and Diamond, 2010).

The classic presentation of intravaginal testicular torsion is the sudden onset of severe, unilateral pain that is often associated with nausea and emesis. The abdomen and inguinal area should be inspected for other causes of scrotal pain such as an inguinal hernia. Scrotal exam findings often include a higher riding testicle in the hemiscrotum, a transverse orientation, an anterior epididymis, absent cremasteric reflex, tenderness of the testicle and epididymis, and a firm testis. High-resolution ultrasound with color-flow Doppler can provide information about testicular blood flow. However, significant ischemic damage is believed to occur after 4 to 8 hours, and thus testicular torsion represents a true surgical emergency that should not be delayed awaiting confirmatory imaging (Bartsch et al., 1980).

Torsion of the Testicular or Epididymal Appendix.

The testicular appendix is a remnant of the müllerian duct, whereas the epididymal appendix is of wolffian duct origin (Gatti and Patrick Murphy, 2007). Torsion of an appendage occurs more commonly in the prepubertal age group, and presentation can mimic testicular torsion with a sudden onset of pain, nausea, and vomiting. Physical exam demonstrates localized tenderness at the superior pole of the testis or caput epididymis and is often associated with a reactive hydrocele. In boys with thin scrotal skin, the classic "blue dot" sign, reflective of a necrotic appendix, is seen (Fig. 23.1).

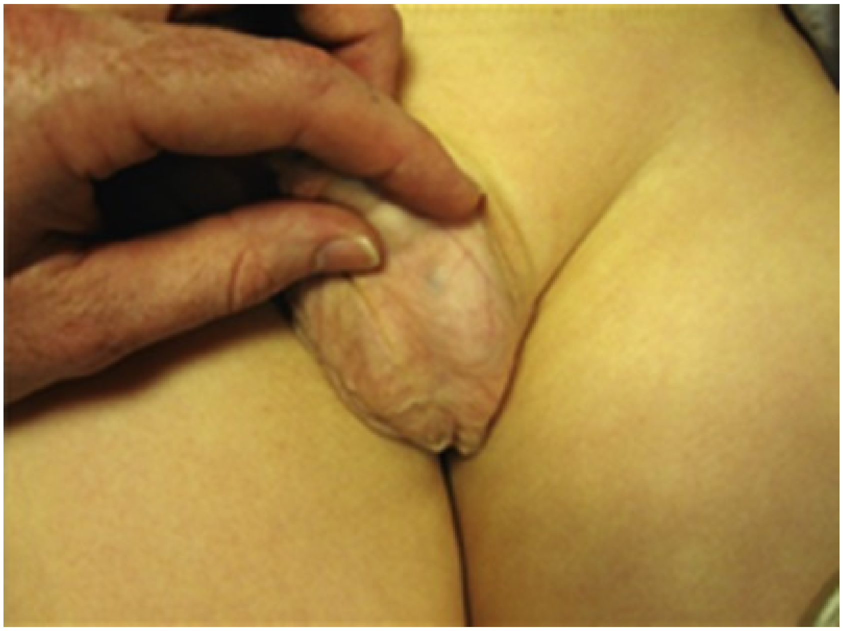

FIG. 23.1 Blue dot sign. Torsion of a testicular or epididymal appendage can mimic testicular torsion. Physical exam demonstrates localized tenderness at the superior pole of the testis or caput epididymis. In boys with thin scrotal skin, the classic "blue dot" sign is seen, reflective of a necrotic appendix.

Ultrasound showing the discrete appendage can be diagnostic, but a later study may only show increased blood flow to the adjacent epididymis and testis, resulting in the misdiagnosis of acute epididymitis or epididymo-orchitis (Rolnick et al., 1968). Pain is most responsive to nonsteroidal anti-inflammatory medications and resolves as the appendage infarcts and necroses. No further intervention is indicated.

Epididymo-orchitis.

Acute epididymitis accounts for up to 35% of pediatric cases of acute scrotal pain and is managed nonoperatively (Lewis et al., 1995). Epididymitis has a gradual onset of scrotal pain and swelling, usually without accompanying nausea. Color-flow Doppler sonography demonstrates increased testicular flow (Tarantino et al., 2001).

Urinalysis classically demonstrates pyuria and bacteriuria, and treatment of these cases is with antibiotics (Gatti and Patrick Murphy, 2007). **However, acute epididymitis associated with bacteriuria only accounts for approximately 15% of the cases of epididymitis, and antibiotics are not indicated for those without pyuria or positive urine culture** (Lau et al., 1997). These cases may be due to viral epididymitis or a postinfectious inflammatory phenomenon, which is usually diagnosed presumptively and is likely to be underreported (Gkentzis and Lee, 2014). In these patients, the condition is self-limiting and management is supportive. In contrast, the occurrence of epididymitis in infants suggests the presence of urinary infection and the likelihood of an associated structural genitourinary abnormality, such as an ectopic ureter, requiring complete urologic investigation (Williams et al., 1979).

Scrotal Mass

Hernia and Hydrocele.

Indirect inguinal herniorrhaphy is one of the most frequently performed surgical procedures in children, occurring up to 10 times more frequently in boys than in girls and also more commonly in premature infants (Brandt, 2008). Pediatric inguinal hernias commonly are seen as inguinal or inguinoscrotal swelling in infancy or new onset of scrotal swelling in older children. The swelling is observed with crying or straining or may be preceded by increasing abdominal pressure resulting from vomiting, constipation, or coughing. The examiner may see this in the office when babies cry or in older children by asking them to blow bubbles or blow up balloons; however, the surgeon may not see the bulge, and some will operate based on a classic description by caretakers or a referring physician, or a photograph obtained by the family. Hernias in children are repaired around the time they are diagnosed, even if they are asymptomatic. **Repair should take place in a timely manner to minimize the risk of incarceration, particularly in infants less than 12 months of age and in preterm infants who have the highest risk** (Brandt, 2008). It is our practice to surgically address hernias within a few weeks of presentation.

A hydrocele is a collection of fluid in the space surrounding the testicle between the layers of the tunica vaginalis, and in many cases they are associated with an indirect inguinal hernia (Kapur et al., 1998). Communicating hydroceles can be identified by a history of enlargement after activity or in the evening as compared with early morning (after being supine). **In the majority of infants, there is no indication for surgery within the first 24 months of age because they resolve spontaneously.** Those that do not develop until the child is several years old, and those associated with an inguinal hernia require surgical repair. The operation performed is high ligation of the patent processus vaginalis, the same procedure as that performed for inguinal hernia repair.

Varicocele.

Varicocele is an abnormal dilation and tortuosity of the internal spermatic veins within the pampiniform plexus of the spermatic cord. Varicocele have an incidence of 15% in adolescence with 90% being left-sided and 10% being right-sided (MacLellan and Diamond, 2006). **The optimal management of adolescent varicocele remains controversial given that 80% of adults with varicocele are fertile. The most commonly accepted indications for surgery in adolescents include hypotrophy of the involved testis, pain, bilateral disease, and varicocele in a solitary testis.**

The patient is examined in a warm room in the supine and standing positions. The scrotum is observed for visible swelling, and the spermatic cord is palpated at rest and during the Valsalva maneuver. They are graded as follows: grade 1, palpated with Valsalva; grade 2, palpated without Valsalva; grade 3, easily visible. Failure of a varicocele to decompress in the supine position, particularly on the right side, is a rare finding and warrants evaluation for a retroperitoneal tumor compressing the spermatic vein (Roy et al., 1989). To assess for testicular hypotrophy, serial testicular volume measurements should be undertaken given testicular asymmetry is common in adolescence (Vaganée et al., 2018). Prader and Rochester orchidometers are valuable in assessing testicular size, although ultrasonography is more accurate (Sakamoto et al., 2007).

Testicular Tumor.

A painless testicular mass is the most common presentation of a child with a testicular tumor. **Testicular tumors account for 1% of all pediatric solid tumors and may occur at any age with peak incidences before 3 years of age and again in the postpubertal period** (Ciftci et al., 2001). Accurate diagnosis of testicular tumors is critical in avoiding diagnostic delay, which results in distant metastases and poor prognosis. Therefore a solid scrotal mass in a child should be considered malignant until proved otherwise. Among malignant lesions, yolk sac tumors account for the majority of malignant tumors in prepubertal boys (Pohl et al., 2004). However, benign lesions, predominantly teratoma, represent nearly three-fourths of testicular tumors in prepubertal boys.

Diagnosing a testicular tumor requires exclusion of scrotal masses such as epididymitis, hernia, hydrocele, and spermatic cord torsion, which can be seen as a painless mass in the neonate. Although transillumination can differentiate if the primary component is fluid, such as a hydrocele, color Doppler ultrasonography is routinely performed to detect intratesticular neoplasms (Tallen et al., 2011). If an intratesticular mass is detected, a thorough examination of the lymph nodes should be performed to evaluate for lymphoma, leukemia, or metastatic disease. Physical examination should also evaluate for signs of precocious puberty, which may indicate the presence of a Leydig cell tumor. Finally, laboratory studies including α-fetoprotein and β-human chorionic gonadotropin should be obtained in any patient with a solid testicular tumor; those with concern for Leydig cell tumor should also be evaluated with serum testosterone and androstenediol levels.

Any suspicion of the malignant testicular tumor warrants radical orchiectomy via an inguinal approach to prevent scrotal violation by the tumor. Testis-sparing surgery may be performed for benign lesions such as teratoma, Leydig cell tumor, and epidermoid cyst based on imaging characteristics and potentially frozen biopsy findings (Woo and Ross, 2015).

Penile Conditions

When performing a penile exam, clinicians should appreciate that physiologic phimosis, or inability to retract the foreskin, is normal until at least 4 years of life and often extends into older age groups (Hayashi et al., 2011). In fact, 90% of foreskins are retractile by 3 years of age with less than 1% of males experiencing persistent phimosis by 17 years of age. These adhesions should not be manually separated if there is no bother (see conditions later) because the foreskin will become retractile over time with penile growth, erections, and smegma production. Notably, the position of the urethral meatus is almost never abnormal in the uncircumcised penis with a circumferential foreskin. Stretched penile length, measured from the pubic symphysis to the tip of the glans, and girth should be measured.

Foreskin

Phimosis and Paraphimosis.

Pathologic phimosis occurs when the prepuce cannot be retracted over the glans penis in older children, often because of inflammatory or traumatic injury resulting in an acquired inelastic scar that prevents retraction (Hayashi et al., 2011). This can cause balanoposthitis (inflammation of the glans and prepuce), dysuria, preputial ballooning during voiding because of urine entrapment, or retained smegma. **Topical corticosteroids are an effective treatment and is a safe, less invasive first-line treatment option before undertaking**

circumcision to correct phimosis (Moreno Corbalán et al., 2014).

Paraphimosis can occur when the foreskin is left retracted behind the glans penis for a period of time. This results in a tight constrictive band of tissue causing vascular engorgement and swelling of the glans, which prevents easy reduction of the foreskin to its anatomic position (Pohlman et al., 2013). **If left unattended, serious injury can occur and thus paraphimosis is a urologic emergency.** Reduction of the paraphimotic ring can be challenging because of severe edema of the tip of the foreskin and requires manual compression of the glans with compression of the edematous foreskin. This can be facilitated by placing a flexible self-adhering bandage around the penis, beginning from the tip and working toward the base, wrapping around the phallus approximately three times with each wrap. The wrap should be left in place for 15 to 20 minutes to reduce the edema. It can then be removed and manual reduction can be employed. In children, this procedure often requires some level of sedation. Subsequent re-wrapping for an additional 15 to 20 minutes may be employed after reducing the foreskin to its anatomic position to prevent recurrence of paraphimosis while the foreskin is inflamed.

Circumcision.

Male circumcision consists of the surgical removal of the foreskin from the penis. It is one of the most common procedures in the world. **Physicians counseling families about elective male circumcision should assist parents by explaining, in a nonbiased manner, the potential benefits and risks and by ensuring that they understand the elective nature of the procedure** (American Academy of Pediatrics Task Force on Circumcision, 2012).

Contraindications to newborn circumcision include significantly premature infants, those with blood dyscrasias, and individuals who have a family history of bleeding disorders. Before proceeding with a newborn circumcision, a thorough examination must be performed. Circumcision should not be performed if there is concern for congenital abnormalities such as hypospadias, suggested by deficient ventral foreskin, congenital penile curvature, deficient shaft skin such as penoscrotal fusion, or congenital buried penis. Occasionally, when the foreskin is retracted before a circumcision, the distal urethra and urethral meatus are enlarged (megameatus intact prepuce); in this case, the circumcision may be canceled in anticipation of formal operative repair. However, repair of this megameatus intact prepuce variant can be performed without an increased complication rate in those whose circumcision was completed (Chalmers et al., 2014; Duckett and Keating, 1989; Snodgrass and Khavari, 2006).

Newborn circumcisions are most commonly performed using the Gomco clamp, the Plastibell device, or the Mogen clamp. Significant acute complications of circumcision are rare, occurring in approximately 1 in 500 newborn male circumcisions (American Academy of Pediatrics Task Force on Circumcision, 2012). Acute complications are usually minor and most commonly involve bleeding, infection, or an imperfect amount of tissue removed. Late complications also occur, most commonly adhesions, skin bridges, and meatal stenosis.

The most common complication, bleeding, is generally minor and can be controlled by pressure on the wound (Lerman and Liao, 2001). Infection is the second most common complication and is also most commonly minor, treatable with local wound care and antibiotics if needed. Notably, the most common complication specifically associated with the Plastibell device is a retained or proximally migrated Plastibell, which occurs in approximately 3.5% of these circumcisions in a large series of 1129 patients. This can be managed by incising the device with a ring cutter, prying it open with hemostats, and removing it (Cilento et al., 1999). The skin should be treated with an ointment with each diaper change until epithelization has occurred.

Late complications can be treated electively as an outpatient surgical procedure as long as voiding remains normal during this period. The most common of these complications is urethral meatal stenosis, which may develop because the glans is no longer protected by the prepuce and the urethral meatus is in contact with ammonia produced by bacteria in urine-soaked diapers. If the stream has an upward deviation, this problem can be easily corrected with a meatotomy (Baskin et al., 1996).

Smegma Pearl or Smegmoma.

This common condition was noted in 5% of healthy children in one series although also is seen by the pediatric urologist as a “penile mass” (Fig. 23.2; Oster, 1976). **Smegma pearls, also referred to as smegmomas, are a benign collection of smegma in the subpreputial space of young uncircumcised boys.** This tends to occur before the ability to retract the foreskin in young boys or if the prepuce is not retracted regularly to clean the glans and coronal sulcus in older boys (Sonthalia and Singal, 2016). It is important to provide education and reassurance to the caretaker that this will resolve with proper hygiene as the prepuce becomes more retractile (Krueger and Osborn, 1986). It is particularly important to advise caretakers that this white or yellow thick material, with a texture and appearance like grits, will eventually emanate from between the foreskin and the glans. It is not infectious, and proper hygiene is the only necessary treatment.

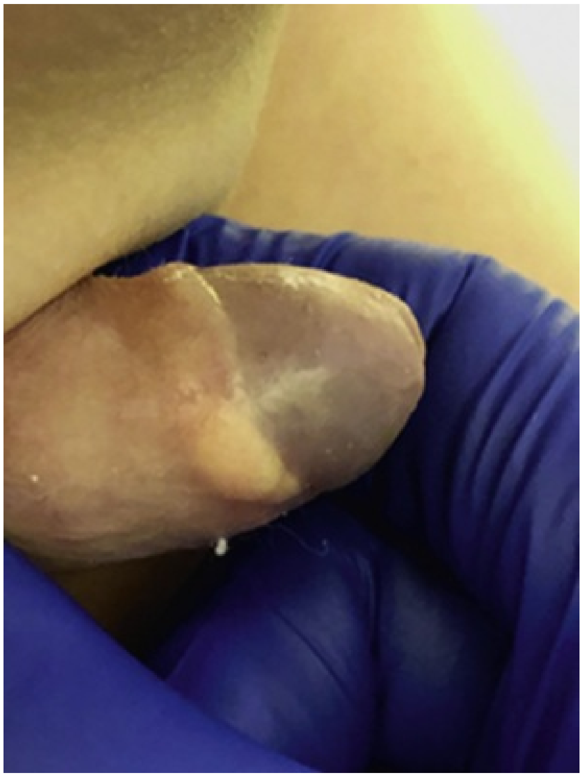

FIG. 23.2 Smegmoma. This common condition is a benign collection of smegma in the subpreputial space of young boys. This tends to occur before the ability to retract the foreskin in young boys or if the prepuce is not retracted regularly to clean the glans and coronal sulcus in older boys.

Inconspicuous Penis.

An inconspicuous penis refers to a penis that appears to be small with a normal stretched penile length measured from the pubic symphysis to the tip of the glans and normal diameter of the penile shaft. These conditions must be differentiated from micropenis, in which the stretched penile length is less than 2.5 standard deviations below the mean size for age (less than 1.9 cm in a full-term neonate) (Aaronson, 1994). If micropenis is diagnosed, evaluation should proceed with karyotype and assessment of the hypothalamic-pituitary-testicular axis.

The nomenclature for this type of penis has been variable in the literature. It is important to carefully examine and appropriately classify the type of inconspicuous penis to provide the appropriate treatment (Crawford 1977; Hadidi, 2014).

Buried Penis.

A buried penis is defined as an apparent absence of the penis characterized by an abnormally long inner prepuce sometimes accompanied by abnormal dartos fascia attachment, abnormal distal attachment of fundiform and suspensory ligaments, and excess suprapubic fat deposition (Hadidi, 2014). In many patients without voiding symptoms, this varied condition can simply be observed. Should treatment be desired, weight loss is first-line therapy and surgical reconstruction remains controversial. However, reconstruction is often indicated in those with congenital megaprepuce who have an abnormally long inner prepuce in conjunction with a phimotic ring causing progressive dilation of the inner foreskin from urine trapping. These patients experience intermittent ballooning and associated UTI and skin irritation.

Concealed Penis.

This acquired condition occurs after circumcision and is seen with a penis retracted behind the circumcision scar in the suprapubic fat pad. Treatment can be initiated with 0.05% betamethasone in conjunction with manual retraction (Palmer et al., 2005). Should this not be successful, surgical correction includes excision of the circumcision scar with possible need for penile skin flaps or Z-plasty for closure.

Webbed Penis.

A webbed penis involves only the inferior penoscrotal junction and the penis is not truly buried (Hadidi, 2014). Surgical correction is relatively straightforward and usually can be achieved by making a V-shaped midline incision that drops the scrotal skin away from the penis.

Abnormal Penile Orientation

Penile Torsion.

Penile torsion is a rotational deformity of the penile shaft, usually in the counterclockwise direction with normal orientation of the corporal bodies (Bauer and Kogan, 2009). This can be an isolated finding or it may be associated with other penile conditions such as hypospadias or curvature. Most forms of penile torsion are mild, primarily of cosmetic significance. Correction is typically indicated only if the rotation is at least 60 degrees and typically involves degloving the penile skin, rotating the glans in the direction opposite to the defect, and suturing the glans to the penile skin. In more severe cases, dorsal dartos flap rotation is an excellent option.

Penile Curvature.

Curvature of the penis may occur along the vertical or horizontal plane of the penis. Penile curvature is most commonly in the ventral direction, referred to as chordee, and is commonly associated with hypospadias. However, chordee may occur without hypospadias. There are three possible causes: (1) ventral skin tethering; (2) corporal disproportion; and (3) tethering by abnormal urethral plate development (Baskin et al., 1996). **Although there may be no cosmetic findings, the severe angulation with erection may interfere with sexual function** (Bennett and Gittes, 1980). Surgical correction is therefore indicated, although the technique will vary depending on the cause and severity of the curvature.

Parameatal Urethral Cyst.

The parameatal urethral cyst is rare anomaly and appears as a small vesicular lesion in proximity to the urethral meatus that does not usually interfere with urinary or sexual function (Fig. 23.3; Shiraki, 1975). To prevent recurrence and obtain an acceptable cosmetic outcome, complete excision can be performed. Care should be taken not to cause meatal stenosis.

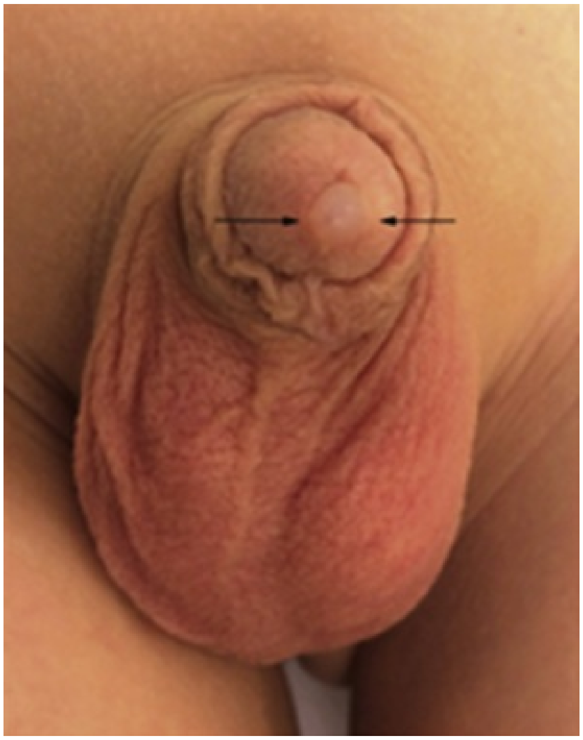

FIG. 23.3 Periurethral cyst. Periurethral cysts are usually asymptomatic, although sometimes are accompanied by dysuria, frequency, urinary stream distortion, or urinary retention.

Hypospadias.

Hypospadias is thought to be an arrest in normal penile development resulting from a combination of genetic and environmental causes with three resultant and related anomalies: a urethral defect with associated abortive corpus spongiosum, a preputial defect with ventral skin deficiency, and chordee (Cunha et al., 2015). It is the second most common congenital anomaly of the genitalia, although prevalence remains uncertain with a recent review noting prevalence ranging from 5 (in South America) to 34 (in North America) per 10,000 live births after reviewing literature screening more than 90,000,000 births (Springer et al., 2016).

If hypospadias is suspected on physical exam, a newborn circumcision should not be performed, and a referral to a pediatric urologist for further evaluation is warranted. The examination of the penis should evaluate the location of the meatus, presence of penile curvature, and assessment of the foreskin because these factors will inform the severity of the hypospadias and the course of treatment (Baskin, 2017)**. Importantly, a testicular exam is critical as the absence of both, or even one, palpable testicle may signal a**

disorder of sex development rather than isolated hypospadias. These patients should be evaluated with a karyotype and possible endocrinology assessment.

Priapism.

Priapism is a persistent penile erection, typically affecting only the corpora cavernosa, unrelated to sexual stimulation that is sustained for greater than 4 hours (Montague et al., 2003).

Priapism can be ischemic (veno-occlusive, low flow), nonischemic (arterial, high flow), and stuttering (intermittent). **All patients with priapism should evaluated immediately to intervene as soon as possible in those with ischemic priapism.** The most common cause in children is sickle cell disease (ischemic).

Evaluation should focus on differentiating ischemic from nonischemic priapism. Understanding the history of the episode is important with focus on degree of pain (only ischemic priapism is painful), history of similar episodes and inciting drugs, history of trauma, and history of hematologic disorders such as sickle cell. Physical exam should evaluate the genitalia because completely rigid corpora cavernosa suggests ischemic priapism; additional attention should focus on signs of trauma or malignancy. If uncertainty remains, laboratory evaluation for signs of blood dyscrasias (such as sickle cell anemia or leukemia), a cavernosal blood gas test assessing for hypoxia, and/or color duplex ultrasonography demonstrating absence of blood flow are diagnostic of ischemic priapism.

Treatment of priapism depends on its cause with sickle cell disease making up the majority of priapism in children, 65% (Donaldson et al., 2014). Treatment of low-flow priapism resulting from sickle cell disease includes concurrent treatment of the underlying disease with transfusion, alkalization, hydration, oxygen, and intracavernous treatment with aspiration (with or without irrigation) or intracavernous injection of sympathomimetics as indicated.

Key Points

- Cryptorchidism is among the most common referrals to pediatric urology, and diagnosis is based on physical exam alone.
- Acute scrotal pain has a wide differential, but testicular torsion must be ruled out because it represents a true surgical emergency.

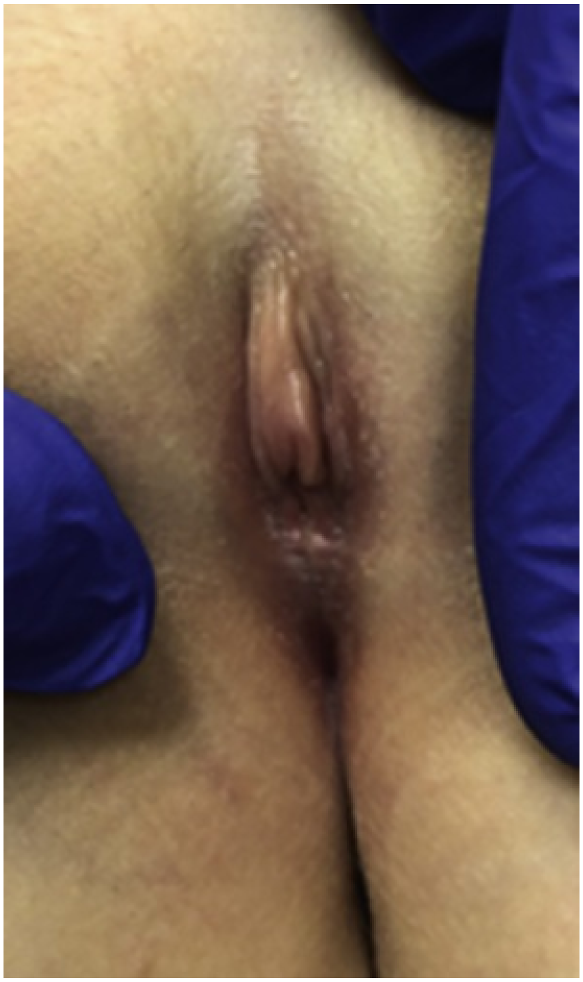
- Topical corticosteroids use is a safe, less-invasive first-line treatment option before undertaking circumcision to correct phimosis if cicatrix is not present.
- If hypospadias is suspected, a newborn circumcision should not be performed and a referral to a pediatric urologist is warranted.
- Evaluation of children with priapism should focus on differentiating ischemic from nonischemic priapism as treatment depends on the cause.

External Genitalia of the Female

The patient should be examined in a warm room in supine position, frog-legged. Examination of the perineum in female infants and young girls should include examination of the urethral meatus, vaginal introitus, and anus. To aid in visualization, the labia majora can be gently grasped and pulled caudally and laterally to enable funneling of the introitus and vagina as demonstrated in Video 23.2 ▶ (Price, 2013). The clitoris is examined for evidence of hypertrophy, which may be suggestive of a disorder of sex differentiation.

Labial Adhesions

Labial adhesions are the most common interlabial anomaly identified in girls with an incidence of 1.8% with a peak incidence between 13 and 23 months (Leung et al., 1993). Fusion of the labia minora originates at the posterior fourchette and progresses for a variable distance toward the clitoris (Fig. 23.4). **Although labial adhesions are usually asymptomatic, urine pooling within the vagina may lead to postvoid dribbling and infection.** Asymptomatic patients should be managed conservatively given spontaneous resolution rates of 80% within 1 year (Bacon et al., 2015). In symptomatic patients, topical treatment with estrogen and/or steroid cream is often curative. Less often, manual separation using topical anesthesia with or without sedation is necessary. **Recurrence is common until a patient goes through puberty.**



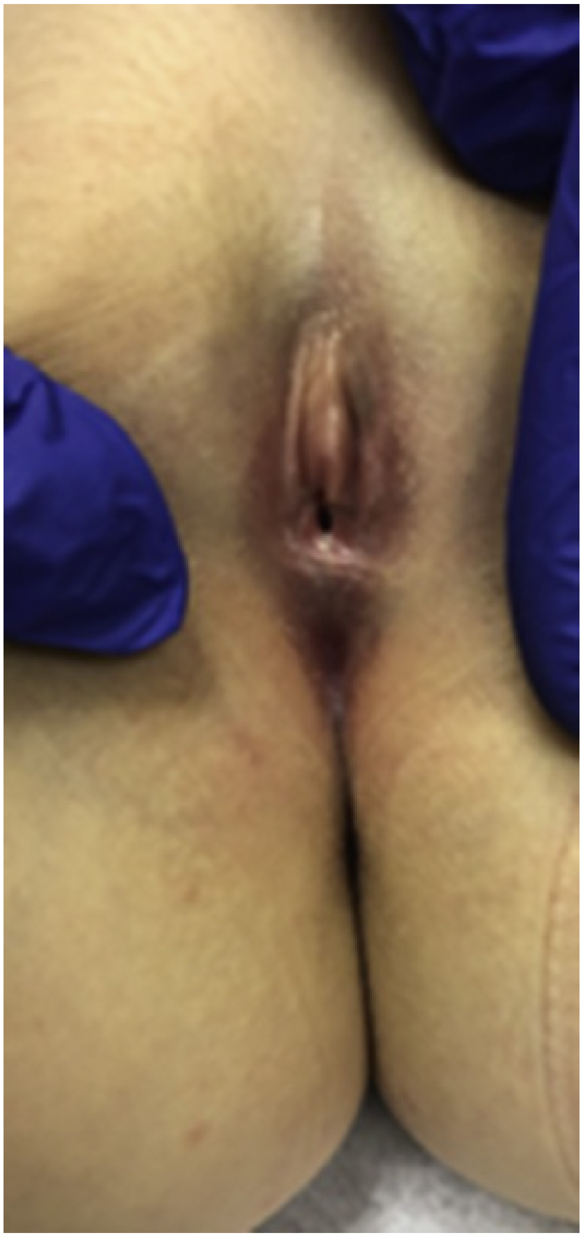


FIG. 23.4 Labial adhesions. Labial adhesions are the most common interlabial anomaly identified in girls. Fusion of the labia minora originates at the posterior fourchette and progresses for a variable distance toward the clitoris. Although labial adhesions are usually asymptomatic, urine pooling within the vagina may lead to postvoid dribbling and infection. Recurrence is common until the patient goes through puberty.

Interlabial Masses

Vaginal masses may be palpable or may protrude from the introitus. The differential diagnosis of interlabial masses is broad, including benign paraurethral cysts, hymen skin tags, urethral prolapse, imperforate hymen, prolapsed ureterocele, or, rarely, malignancies. Although age and racial background can help narrow the differential diagnosis, physical examination remains the most useful tool for determining the specific pathology. **An introital mass should be examined for site of origin, laterality, symmetry, and signs of infection or irritation.** The relationship of the mass to the vagina and urethra can be improved by gentle placement of a lubricated cotton applicator posteriorly or placement of a small feeding tube within the suspected urethral orifice, or both. A carefully performed examination and vaginoscopy under anesthesia may be necessary.

Hymenal Disorders

Imperforate Hymen.

Hymenal abnormalities are the most common outflow tract concern, with imperforate hymen occurring in 1 of 2000 girls (Fig. 23.5; Dietrich et al., 2014). **An imperforate hymen may result in hydrometrocolpos and a lower abdominal mass.** In infancy, examination demonstrates a midline bulging, pearly white membrane. In puberty, the inability to efflux menstrual blood leads to cyclic pelvic pain and primary amenorrhea. Inspection of the vulva reveals no hymenal opening and a bulging or bluish hymenal membrane. **Treatment involves incision of the imperforate hymen, which allows passage of the menstrual contents. No postoperative dilation is indicated because stenosis does not occur.**

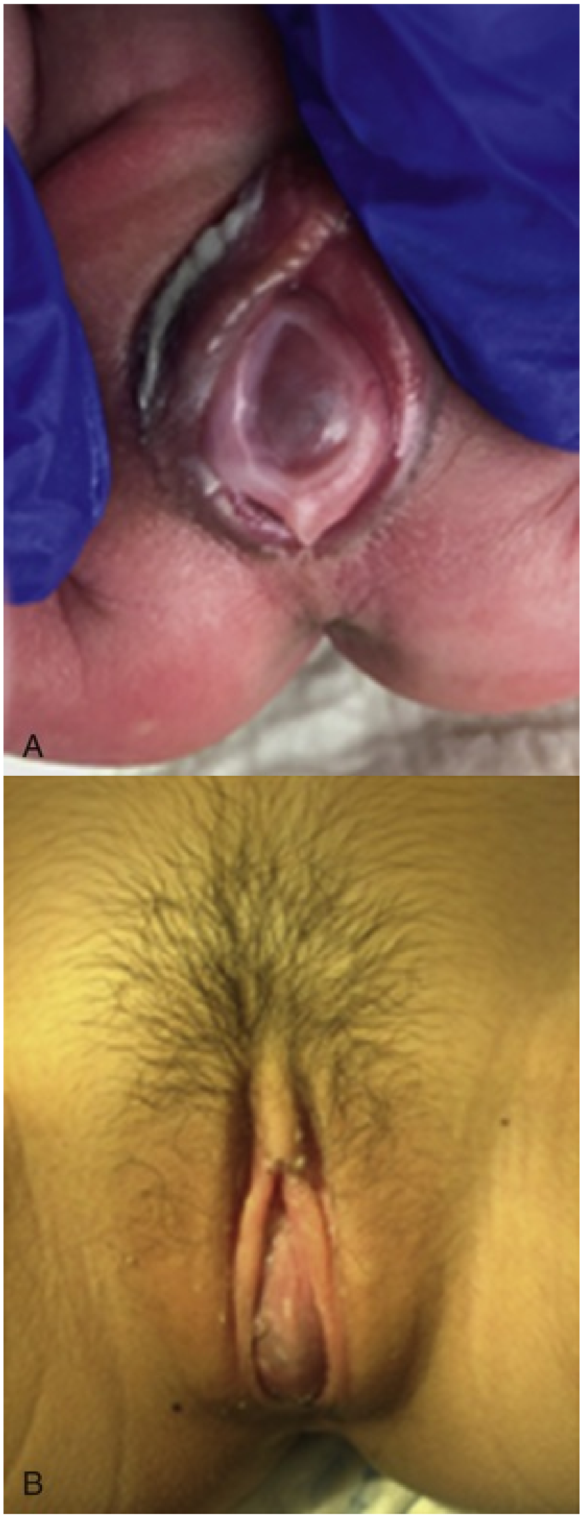

FIG. 23.5 Imperforate hymen. An imperforate hymen may result in hydrometrocolpos. (A) In infancy, examination demonstrates a midline bulging, pearly white membrane. (B) In puberty, the inability to efflux menstrual blood leads to cyclic pelvic pain and primary amenorrhea. Inspection of the vulva reveals no hymenal opening and a bulging or bluish hymenal membrane.

Hymenal Skin Tag.

Hymenal skin tags can cause confusion during examination because they can fall over the hymenal orifice, obscuring it (Price, 2013). It may be necessary to use a swab to delineate the tag and move it so that the rest of the hymen can be visualized. **These are considered a normal variant, are rarely symptomatic, and require no treatment.** When symptomatic, usually with bleeding, they should be excised to provide relief.

Paraurethral Cyst.

Interlabial cysts occur in between 1 : 1000 and 1 : 7000 newborn girls (Badalyan et al., 2012). **Paraurethral cysts, also called Skene cysts, are among the most common neonatal intralabial cysts** (Fig. 23.6). They are thin walled and golden or whitish and anterior to the vagina, rarely causing symptoms such as urinary stream deviation. When positively identified, no evaluation of upper urinary tract is required, and they are most often self-resolving. If persistent or symptomatic, paraurethral cyst incision may be performed. A careful, well-focused physical examination helps the clinician differentiate between this benign self-condition and other interlabial lesions.

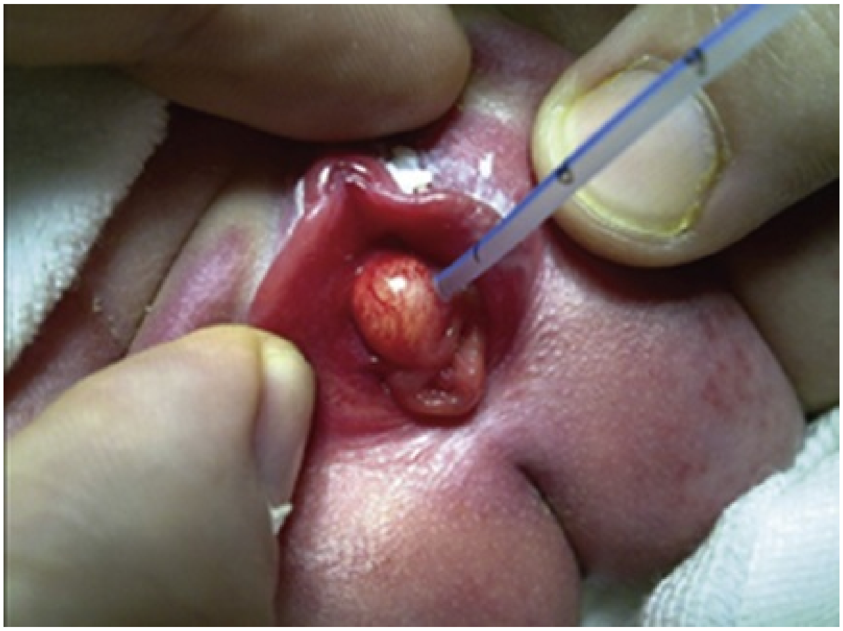

FIG. 23.6 Paraurethral cyst. Paraurethral cysts are among the most common neonatal intralabial cysts. They are thin walled and golden or

whitish and anterior to the vagina, rarely causing symptoms such as urinary stream deviation. A careful physical examination helps differentiate between this benign condition and other interlabial lesions.

Urethral Prolapse

Urethral prolapse is a circular eversion of mucosa protruding through the external meatus occurring most commonly in prepubertal black girls and in postmenopausal white women (Fig. 23.7; Richardson et al., 1982). Presentation in prepubertal girls usually results from vaginal bleeding resulting from contact of the friable, prolapsed mucosa with undergarments; voiding dysfunction is uncommon. Historically, treatment has comprised surgical manipulation (Fernandes et al., 1993; Redman, 1982). **Nonoperative treatment such as topical estrogen, corticosteroids, and sitz baths has resulted in reduction of the prolapse, although a high recurrence rate suggests that definitive surgical excision may still be required** (Jerkins et al., 1984). Although the cause of urethral prolapse is likely multifactorial, episodic increases in intra-abdominal pressure are likely contributory (Lowe et al., 1986). Therefore the authors recommend patients with urethral prolapse be screened and treated as necessary for underlying constipation.

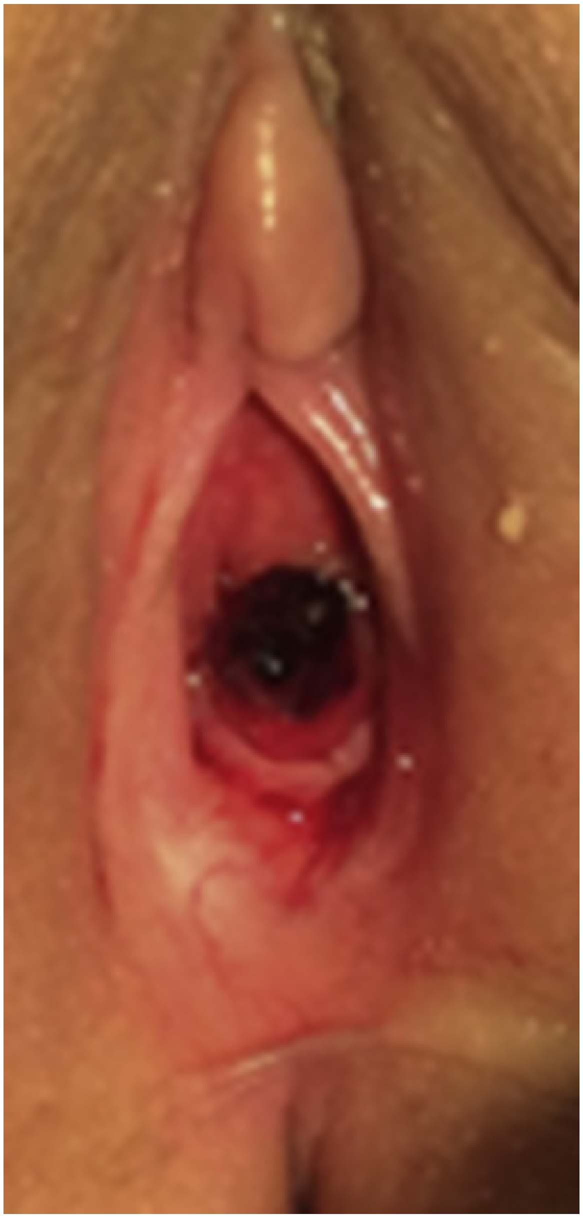

FIG. 23.7 Urethral prolapse. Urethral prolapse is a circular eversion of mucosa protruding through the external meatus occurring most commonly in prepubertal black girls and in postmenopausal white women. Presentation in prepubertal girls usually results from vaginal bleeding because of contact of the friable, prolapsed mucosa with undergarments.

Prolapsing Ureterocele

Ureteroceles represent a version of the ectopic ureter with a cystic dilation of the distal aspect of the ureter that is located either within the bladder or spanning the bladder neck and urethra. An important subgroup to recognize, referred to as ectopic or cecoureteroceles, are ureteroceles in which some portion of the ureterocele extends beyond the bladder neck into the urethra (Fig. 23.8; Glassberg et al., 1984). This may cause bladder outlet obstruction.

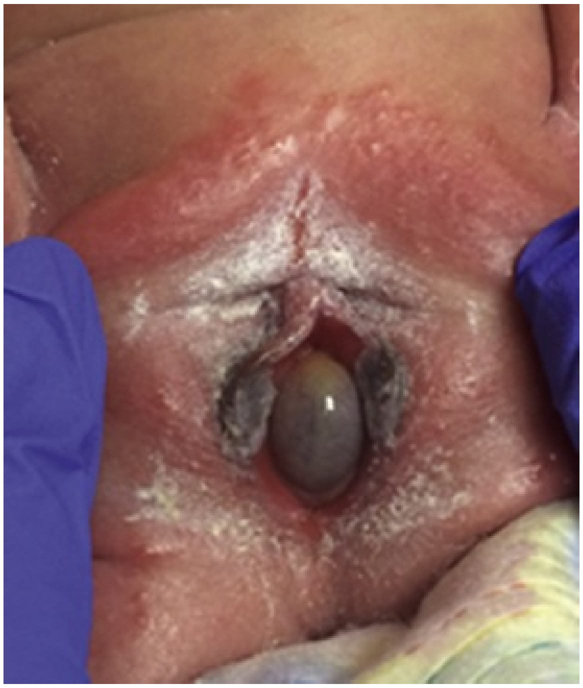

FIG. 23.8 Prolapsing ureterocele. Ureteroceles represent a version of the ectopic ureter with a cystic dilation of the distal aspect of the ureter that is located either within the bladder or spanning the bladder neck and urethra. An important subgroup to recognize are those in which some portion of the ureterocele extends beyond the bladder neck into the urethra, which may cause bladder outlet obstruction. Physical examination will demonstrate a smooth, congested, mucosa-covered interlabial mass protruding from the urethra that is distinct from the vagina.

History may reveal voiding difficulty resulting from urethral obstruction. Physical examination will demonstrate a smooth, congested, mucosa-covered interlabial mass protruding from the urethra that is distinct from the vagina. This can be differentiated from urethral prolapse because the ureterocele is not circumferential. **The diagnosis can be confirmed with a renal bladder ultrasound. Definitive surgical treatment differs depending on the patient's anatomy; however, initial treatment should begin with incision or endoscopic puncture of the ureterocele to relieve urethral obstruction** (Glassberg et al., 1984).

Vaginal Rhabdomyosarcoma

Primary vaginal tumors present at a mean age of less than 2 years (Hays et al., 1988). **The rhabdomyosarcoma botryoides subtype of rhabdomyosarcoma is most often described as a grapelike cluster of tissue emanating from the posterior aspect of the vestibule** (Aalia Sachedina et al., 2018). Diagnosis is confirmed with tissue biopsy and evaluation consists of staging imaging followed by chemotherapy and local excision in some circumstances.

Vaginal Discharge

Vaginal discharge is the most common gynecologic complaint in young girls. When treating young children with vaginal discharge, clinicians must understand the causes so that the condition can be adequately investigated and treated (McGreal and Wood, 2013).

Bladder and Bowel Dysfunction

Dysfunctional voiding is a common concern exhibited by approximately 40% of patients seen by the pediatric urologist (Farhat et al., 2000). Voiding dysfunction in children encompasses a variety of clinical entities typically occurring after toilet training; it may originate from behavioral issues that arise around this time in childhood development. The International Children's Continence Society developed standardized definitions to establish uniformity and clarity in the characterization of lower urinary tract function and dysfunction in children across multiple health care disciplines (Austin et al., 2014). Concomitant bladder and bowel disturbances have been labeled as bladder and bowel dysfunction (BBD). **Given its breadth of urinary symptoms, it is discussed later more completely in the urinary tract section.**

Patients with BBD may experience postmicturition dribbling, which can be confused with vaginal discharge. Elsewhere referred to as vesicovaginal reflux, postvoid dribbling, or vaginal voiding, this is observed in otherwise normal prepubertal girls after toilet training (Feldman and Bauer, 2006). During voiding, urine passes into the vagina, and this pooled urine dribbles out during standing, wetting the underwear. This occurs in patients who do not void with their legs wide enough apart to allow passage of urine, sometimes because of an obese or overweight habitus. This resolves with age and growth. In the interim, the child may be taught to empty her vagina by sitting faced backward on the toilet or manually spreading the labia during voiding.

Foreign Body

Recurrent or persistent vaginal discharge is distressing to the patient and her family. Foreign bodies, although an uncommon cause of vaginal discharge, must be considered. **Foreign bodies account for 4% of girls under 13 years of age with genitourinary complaints and 10% of the girls with a complaint of bloody discharge** (Smith et al., 2002). The most common foreign body is toilet paper. Ruling out a foreign body requires a careful genital examination in the clinic, and procedures such as a vaginal saline lavage (in cooperative patients) or an examination under anesthesia with vaginoscopy, which allows for a more thorough examination and for obtaining vaginal cultures and biopsies, if indicated.

Sexual Abuse

Sexual abuse is a prevalent reality in pediatric medicine and must be considered based on presentation with symptoms including vaginal, penile, or rectal pain, discharge, or bleeding, vulvovaginitis, and enuresis**. Given its impact beyond the female external genitalia, it will be discussed later in the urinary tract section.**

Other Vaginal Disorders

Patients with primary amenorrhea, the absence of menses at age 15 years, with normal growth and secondary sexual characteristics may have genitourinary anomalies. Evaluation should include a careful physical exam. The assessment should include breast development, as assessed by Tanner staging, growth (height, and weight), skin findings (hirsutism, acne, striae, increased pigmentation, vitiligo), and a careful genital examination for clitoral size, pubic hair development, intactness of the hymen, vaginal length, and presence of a cervix, uterus, and ovaries. If a normal vagina or uterus is not obviously present on physical examination, pelvic ultrasonography should be performed to evaluate for ovaries, uterus, and cervix.

Should the uterus be absent, evaluation may proceed with a karyotype and testosterone measurement to assess for vaginal atresia (müllerian agenesis, Mayer-Rokitansky-Küster-Hauser syndrome) versus disorders of sex development associated with 46, XY karyotype such as complete androgen insensitively syndrome or 5-alpha reductase deficiency. Management of each of these anomalies is complex and must balance the priorities of the patient as well as his or her parents considering psychological and anatomic ramifications of treatment options.

Should the uterus be present, outflow tract obstruction should be considered. As discussed earlier, one such obstructive pathology is imperforate hymen, which prevents efflux of menstrual blood, leading to cyclic pelvic pain and primary amenorrhea. This can be diagnosed on physical exam by inspection of the vulva revealing no hymenal opening, sometime with a bulging or bluish hymenal membrane. Treatment with surgical incision is definitive. Less commonly, a transverse vaginal septum may be present (Edmonds, 2003). Resulting from incomplete fusion between the müllerian duct component of the vagina and the urogenital sinus component, this incomplete vertical fusion leaves a transverse vaginal septum. Treatment involves surgical excision of the septal defect with a vaginal end-to-end anastomosis between the upper and lower portions of the vagina. Last, vaginal agenesis may be present, occurring in 1 in 5000 women (Kimberley et al., 2012). Although this may be an isolated müllerian anomaly, it may alternately be a consequence of failed induction of the müllerian duct secondary to anomalous wolffian duct formation. Therefore renal anomalies should be assessed with a renal bladder ultrasound.

Key Points

- The differential diagnosis of interlabial anomalies is broad and requires a careful physical examination for accurate diagnosis.
- Vaginal discharge is the most common gynecologic complaint in girls, and the examiner must consider foreign objects and sexual abuse as well as postmicturition dribbling.

Urinary Tract

Urinary Tract Infection and Pyelonephritis

Pediatric UTIs constitute a significant health burden on society, affecting an estimated 2.6% to 3.4% of children yearly and resulting in more than 1 million physician visits annually (Freedman and Urologic Diseases in America, 2005)**. Throughout childhood, the risk of UTI is 2% for boys and 8% for girls. Although female infants have a two- to fourfold higher prevalence of**

UTI than male infants, the prevalence of UTI is highest in boys younger than 1 year of age (Shaikh et al., 2008)**. Among boys, an uncircumcised boy has a tenfold higher risk of UTI compared with a circumcised boy.** In fact, circumcision is associated with decreased odds of UTI among boys with hydronephrosis (odds ratio 0.36, 95% confidence interval 0.29–0.44; Ellison et al., 2018). Given the association of UTI renal scarring that may lead to hypertension, proteinuria, and permanent renal damage, accurate diagnosis and treatment of UTI is important (Jakobsson et al., 1994).

Symptoms of UTI vary with patient age. Neither clinical symptoms nor laboratory tests will predict a UTI in febrile infants, and thus obtaining a urinary specimen is necessary (Crain and Gershel, 1990). Children younger than 2 years old often experience vague symptoms, including fever, irritability, poor feeding, vomiting, diarrhea, and ill appearance with increased likelihood of UTI in the setting of at least two of the following risk factors: (1) age less than 12 months, (2) white race, (3) absence of other fever source, (4) fever greater than 39°C, and (5) fever of 2 or more days (Subcommittee on Urinary Tract Infection, 2011). However, older children and adolescents may localize symptoms to the urinary tract, reporting dysuria, suprapubic pain, voiding dysfunction, incontinence, or flank and/or abdominal pain. There are no specific physical exam signs for UTI, although palpation in the suprapubic and flank areas may cause pain in the older child.

Pyelonephritis refers to an infection of the kidneys and is the most severe form of UTI in children. Clinically, this is associated with systemic features such as high fever, malaise, vomiting, abdominal and flank pain and tenderness, poor feeding, and irritability in infants (Strohmeier et al., 2014). Pyelonephritis is associated with significant short-term morbidity, including shock and septicemia, as well as acute kidney parenchymal injury. Permanent kidney damage may occur after acute pyelonephritis and is more frequent in children who have multiple episodes or who have vesicoureteral reflux.

Guidelines from the American Academy of Pediatrics and the National Institute for Health and Care Excellence recommend urine testing if treating a child for a suspected UTI (National Institute for Health and Clinical Excellence 2007, Subcommittee on Urinary Tract Infection, 2011). **Specifically, a noncontaminated urine sample should be collected, which requires catheterization or suprapubic aspiration in infants and young children who have not completed toilet training.** The diagnosis of UTI is generally confirmed by the pure growth of a bacteria of greater than 10^3 CFU/mL from a suprapubic aspirate or 10^4 CFU/mL from a bladder catheter specimen (Strohmeier et al., 2014). **In addition, adolescents should be evaluated for sexually transmitted infections.** Once a UTI is diagnosed, antimicrobial treatment should proceed based on local antibiograms. Importantly, even the most severe form of UTI in children, acute pyelonephritis, can be treated with oral antibiotics as long as the child can tolerate oral medication (Strohmeier et al., 2014).

Evaluation of children diagnosed with a UTI with imaging remains controversial. Imaging may detect renal damage from an acute infection as well as identify genitourinary anatomy that increases risk of future infection. Acute imaging with ultrasonography is recommended by the American Academy of Pediatrics and by the National Institute for Health and Clinical Excellence Guidelines (NICE); however, the NICE guidelines specifically recommend ultrasound only when the UTI is atypical (a child who is seriously ill, has poor urine flow, an abdominal or bladder mass, a raised creatinine, septicemia, fails to respond to suitable antibiotics within 48 hours, or is infected with non-*E. coli* organisms) (National Institute for Health and Clinical Excellence, 2007). Further imaging with a voiding cystourethrogram is recommended by the American Academy of Pediatrics in children 2 to 24 months only if the renal ultrasound reveals hydronephrosis, scarring, or other findings that would suggest either high-grade vesicoureteral reflux or obstructive uropathy (Subcommittee on Urinary Tract Infection, 2011). A voiding cystourethrogram is also recommended in other complex clinical circumstances such as a recurrent febrile UTI.

Vesicoureteral Reflux

Recurrent UTI occurs in up to 30% of children and occurs more commonly in those with VUR (Williams and Craig, 2011). VUR entails retrograde flow of urine from the bladder to the upper urinary tract and is graded from I to V based on the appearance of the ureter, renal pelvis, and calyces as seen on the radiographic contrast images generated by the voiding cystourethrogram (Duckett and Bellinger, 1982). Although spontaneous resolution of low-grade VUR is common, persistent VUR and UTI may detrimentally affect overall health and renal function. **Controversy exists regarding when to evaluate for VUR and the optimal management strategies including continuous antibiotic prophylaxis and/or surgical intervention.**

As discussed earlier, the American Academy of Pediatrics recommends obtaining a voiding cystourethrogram in children 2 to 24 months in the setting of recurrent febrile UTI or if a renal ultrasound reveals hydronephrosis, scarring, or other findings that would suggest high-grade VUR (Subcommittee on Urinary Tract Infection, 2011). The American Urological Association Guidelines regarding the Management and Screening of Primary VUR in Children further guide the screening of children for VUR (Peters et al., 2010a,b). Neonates with prenatal hydronephrosis have an approximately 16% incidence of VUR (female incidence is greater than male), and a voiding cystourethrogram is recommended for children with high-grade hydronephrosis (Society of Fetal Urology grade 3 and 4), hydroureter, or an abnormal bladder on ultrasound. Given a 27% prevalence of VUR in siblings of children with VUR, a voiding cystourethrogram or radionuclide cystogram is also recommended for these children if there is evidence of renal cortical abnormalities, renal size asymmetry on ultrasound, or if there is a history of UTI in the sibling who has not been tested.

The management of this pathology remains controversial, and these guidelines provide management strategies with aims of preventing recurrent febrile UTIs, preventing renal injury, and minimizing the morbidity of treatment and follow-up. In children older than 1 year of age, continuous antibiotic prophylaxis is recommended in the setting of BBD given the increased incidence of breakthrough UTI in these children. Continuous antibiotic prophylaxis is an option in (a) children less than 1 year of age with Grades I and II vesicoureteral reflux identified through screening or (b) those more than 1 year of age with any grade of VUR who do not have BBD, recurrent febrile UTI, or renal cortical abnormalities.

Bladder and Bowel Dysfunction

BBD is an umbrella term that includes lower urinary tract dysfunction and bowel dysfunction (Austin et al., 2014). **Patients with BBD experience a spectrum of symptoms and require a thorough history to guide therapy. The history should be obtained from the caretaker as well as the child because their perceptions may differ.**

Patients with BBD may have storage and voiding symptoms. Storage symptoms include urinary frequency, urgency, and nocturia as well as urinary incontinence. The examiner should further assess incontinence as continuous versus intermittent. Intermittent incontinence should be further categorized as daytime incontinence (occurring only while awake) and enuresis (occurring during sleeping periods). Voiding symptoms include hesitancy, straining, weak stream, intermittency, and dysuria. Other behaviors such as holding maneuvers, the sensation of incomplete emptying, and pain should be assessed. The examiner should also specifically inquire about the course of toilet training, whether there was an asymptomatic period, and whether there is any history of UTIs. The close relationship between bladder and bowel function requires screening of bowel dysfunction, preferably with a bowel diary using the Bristol Stool Form Scale (Nevéus et al., 2010). Finally, the examiner must differentiate patients whose symptoms are due to other underlying causes. For example, continuous leakage may suggest an ectopic ureter. Symptoms consistent with detrusor sphincter dyssynergia may be due to occult spinal dysraphism. Urinary retention may be caused by posterior urethral valves.

BBD plays a substantial role in development of recurrent UTI (Yang et al., 2017). Rectal distention can compress the adjacent bladder neck and trigonal region, leading to detrusor overactivity and possibly bladder outlet obstruction. The correlation between constipation and UTI may be due to increased uropathogenic organisms in the gastrointestinal tract leading to recurrent infection. Furthermore, improvement in BBD may prevent bacterial adherence, thereby preventing UTI. Moreover, children with BBD and any degree of VUR had the highest risk of recurrent UTI (Keren et al., 2015). BBD is also associated with a decrease in the spontaneous resolution rate of VUR in children receiving continuous antibiotic prophylaxis (Peters et al., 2010a,b).

A focused physical examination should evaluate the back for signs of occult spinal dysraphism as well as lower extremities for signs of weakness. The urologic exam should inspect the location and patency of the urethral meatus in boys and the introitus in girls. Depending on the history and physical exam findings, additional testing to evaluate suspected diagnoses may include a uroflow, postvoid residual, renal and bladder ultrasound, plain film for stool burden, voiding cystourethrogram, and urodynamic evaluation.

Methods of treating BBD must be tailored to the patient's symptoms. Importantly, basic management of BBD consists of behavioral modification therapy, also known as urotherapy, which includes improved hydration, timed voiding every 2 to 3 hours, and an adequate bowel regimen to properly manage constipation (Palmer, 2016). Successful treatment of urinary symptoms depends on thorough management of bowel issues. To minimize the impact of BBD on recurrent UTI, continuous antibiotic prophylaxis is recommended by the American Urologic Association for children with BBD and any grade of VUR.

Urinary Incontinence

Urinary incontinence is a very common problem in children. Development of bladder control begins when the child becomes aware of bladder filling, then develops the ability to suppress detrusor contractions voluntarily, and finally learns to coordinate sphincter and detrusor function (Jansson et al., 2005). Daytime urinary continence typically occurs by 4 years of age followed by night continence, generally achieved by 5 to 7 years of age. **Bladder capacity is based on the age and weight of the patient, equal (in millimeters) to**

$$\text{Weight (kilograms)} \times 8$$

in children less than 2 years of age, and

$$(\text{Age [years]} + 2) \times 30$$

in children greater than 2 years of age (Koff, 1983).

Urinary incontinence, particularly in those who never achieved continence, may be secondary to neurogenic causes, such as tethered cord, or other anatomic causes, such as an ectopic ureter. Alternately, urinary incontinence may be associated with other conditions including BBD and UTI, discussed in detail earlier. A child with urinary incontinence should be evaluated with a thorough history and physical considering this differential.

Sexual Abuse

Sexual abuse must be considered based on presentation with a range of symptoms including vaginal, penile, or rectal pain, discharge, or bleeding, vulvovaginitis, and enuresis. Sexual abuse of children is a prevalent reality in pediatric medicine; it is estimated to victimize 12% to 25% of girls and 8% to 10% of boys by the age of 18 (Anderson et al., 2014). Sexually transmitted diseases are often detectable in cases of sexual abuse. However, the diagnosis of sexual abuse is often made by the history and not by the physical examination because even girls who report repetitive penetrative penile-genital contact have no definitive evidence of penetration on examination of the hymen (Anderst et al., 2009a,b). Investigating sexual abuse requires detailed history taking and may be enhanced by consultation with a child abuse pediatrician specialist for a second opinion. If abuse is suspected, it must be reported to the police (Anderst et al., 2009a,b).

Flank Pain

Nephrolithiasis.

Pediatric nephrolithiasis is a growing public health burden with a 6% to 10% annual rise in incidence over the past 20 years with a mean annual incidence of 36 to 57 per 100,000 children in US population-based observational studies (Van Batavia and Tasian, 2016). Interestingly, the incidence of stones is increasing most drastically among adolescent girls and African-Americans, although the risk of stones is highest among boys in the first decade of life and girls in the second decade of life, returning to a male predominance in the third decade of life. **Notably, the majority of studies show no association between the body mass index and pediatric nephrolithiasis**. Other hypotheses explaining this increasing prevalence include a decrease in fluid intake, an increase in sugar-sweetened soft drinks, climate change, dietary sodium intake, incidental diagnosis, and comorbidities including hypertension and diabetes (Clayton and Pope, 2011).

Most children with nephrolithiasis experience abdominal or flank (renal colic) pain (Gearhart et al., 1991). Similar to adults with nephrolithiasis, the intensity of pain can vary and is often milder and less specific in younger children. Other symptoms may include gross hematuria, dysuria and urgency, and nausea/vomiting. Notably, 15% of pediatric patients with nephrolithiasis are diagnosed because of stone detection when abdominal imaging is performed for other purposes.

When nephrolithiasis is suspected, diagnostic evaluation begins with a thorough history focusing on patient or family history of nephrolithiasis, genitourinary tract structural abnormalities, metabolic conditions associated with stone formation such as malabsorption, medications associated with stone formation, and a history of recurrent UTI. Physical examination should attempt to localize pain and evaluate for fever. In addition, laboratory evaluation should evaluate for urine infection. Finally, the diagnosis of nephrolithiasis is confirmed by the detection of a stone. **When choosing the imaging modality, clinicians must consider that children are at increased risk from radiation exposure as well as recurrence with longer follow-up times given their longer life**

expectancies. Ultrasound imaging should be used for initial diagnostic imaging, reserving CT for those with a nondiagnostic ultrasound in whom the clinical suspicion for stones remains high (Tasian and Copelovitch, 2014). As with adults with nephrolithiasis, the initial step in acute management is determining the need for immediate urinary decompression, reserved for children with obstructed UTI or evidence of pyelonephritis, solitary kidney, or intractable pain, nausea, or emesis (Van Batavia and Tasian, 2016). Decompression can be performed with placement of a retrograde ureteral stent placement or a percutaneous nephrostomy tube. Nonacute management options include observation with pain control, medical expulsive therapy, and surgery. Alpha-blockers are recommended as first-line medical expulsion therapy in children, especially when stones are small and in a more distal ureteral location. **Surgical management is similar to that in adults**: extracorporeal shock wave lithotripsy and ureteroscopy for smaller stones and percutaneous nephrolithotomy reserved for larger renal stone burden. Last, **a metabolic evaluation is recommended, although the impact on mitigating the risk of recurrent stones in children is unknown, particularly in the context of the long-term compliance required** (Tasian and Copelovitch, 2014).

Pyelonephritis.

Pyelonephritis is a significant source of health care use and expenditure, with an inpatient hospitalization rate of 31 per 100,000 children in California in 2005, costing roughly $13.3 million (Copp et al., 2011). As discussed earlier, its presentation is dependent, in part, on the age of affected children and their ability to localize and articulate their symptoms. Older children and adolescents may report flank pain and should be evaluated with a clean-catch urine specimen to evaluate for underlying UTI and pyelonephritis. For further details of evaluation and treatment, see the section on UTI and pyelonephritis, earlier in the chapter.

Ureteropelvic Junction Obstruction

A ureteropelvic junction (UPJ) obstruction is a partial or complete restriction of the flow of urine from the renal pelvis to the ureter, which may be congenital or acquired (Koff et al., 1986). Congenital UPJ obstruction is usually caused by intrinsic stenosis of the proximal ureter at the UPJ, and less commonly by extrinsic compression, usually by an accessory renal artery, of the UPJ. Obstruction occurs more commonly in boys and more commonly in left renal units; bilateral involvement is 10% to 40% (Johnston et al., 1977).

Clinical presentation varies significantly by patient age. Most cases of UPJ obstruction are diagnosed during prenatal ultrasound; UPJ obstruction is the most common cause of prenatal hydronephrosis, occurring in up to 30% of patients found to have urinary tract dilation on prenatal ultrasound (Nguyen et al., 2014). In the absence of prenatal screening, newborns may have a palpable abdominal mass, UTI, hematuria, or failure to thrive. In contrast, older children experience intermittent flank or abdominal pain with nausea and vomiting, worse during brisk diuresis after, for example, caffeine or alcohol (Dietl's crisis) (González and Schimke, 2001). Other presenting signs may include hematuria, nephrolithiasis, or hypertension. For these children, ultrasonography should be performed during the acute painful episode to identify the presence of hydronephrosis. **Although UPJ obstruction is the most common anatomic cause of hydronephrosis, further imaging evaluation with diuretic renography characterizes the severity of UPJ obstruction**. Although UPJ obstruction is usually an isolated anatomic finding, approximately 10% of patients with UPJ obstruction have VUR. This is about a threefold increase compared with the general pediatric population. However, the VUR is often low grade and does not warrant routine screening in the absence of other risk factors such as hydroureter or recurrent UTI (Weitz and Schmidt, 2016).

Although not all patients with partial UPJ obstruction require intervention, severe UPJ obstruction will lead to progressive renal deterioration. Surgical pyeloplasty is indicated in asymptomatic patients with imaging signs of poor drainage (obstructive excretory curve on diuretic renography), renal deterioration (loss of renal function on renography), or progressive hydronephrosis on ultrasonography as well as for symptomatic children.

Gross Hematuria

Gross hematuria is defined by the presence of red blood cells in the urine that are visible to the naked eye, which can be confirmed with a urine dipstick for blood. Although this condition is uncommon, 0.13% of children seen in an emergency walk-in clinic, most children have an easily apparent cause (Diven and Travis, 2000). The most common diagnoses are UTI (26%), perineal irritation (11%), trauma (7%), meatal stenosis with ulceration (7%), coagulation abnormalities (3%), and nephrolithiasis (2%). Less common causes of gross hematuria include sickle cell disease/trait, glomerular disease, malignancies, and benign idiopathic urethrorrhagia. This differential diagnosis substantiates the importance of initiating evaluation of children with gross hematuria with a thorough history, physical examination, laboratory examinations including urinalysis and urine culture, and renal sonogram. Persistent gross hematuria without identifiable cause warrants cystoscopy with retrograde pyelograms. The role of newer imaging techniques such as MR urography as a replacement for cystoscopy and retrograde pyelography is being investigated in the adult setting (Gandrup et al., 2014; Lee et al., 2010). Generalizability to the pediatric setting, with a lower rate of urothelial carcinoma, is uncertain. If the cause of the gross hematuria is not apparent from these investigations, the child should be referred to a pediatric nephrologist, particularly in the setting of proteinuria.

Microhematuria

Microscopic hematuria is a common finding on urine dipstick examination and is confirmed as more than five red blood cells per high-power field on more than two occasions (Feld et al., 1998). Although the differential is wide, most cases are diagnosed as idiopathic or benign. Laboratory and radiographic evaluation, as well as the indications for a renal biopsy, are disputed. However, in the absence of urinary crystals, casts, or proteinuria or a family history of progressive renal disease, most patients may be observed and retested in 6 to 12 months.

Benign Idiopathic Urethrorrhagia.

Bloody spotting of the underwear in prepubertal and pubertal boys has been termed urethrorrhagia. Its cause remains elusive. Mean age at presentation is 10 years old with up to one-third of boys reporting concomitant dysuria (Walker et al., 2001). Evaluation with urine culture and ultrasonography is uniformly normal, and thus management with watchful waiting is recommended. **Complete resolution occurs in more than 90% of patients by 2 years. Thus further evaluation with retrograde urethrography or cystoscopy may be considered to evaluate for urethral stricture if symptoms persist beyond 2 years.** Notably, boys with urethrorrhagia appear to be at increased risk for urethral stricture, and instrumentation should be used judiciously in these patients.

Referral for Ultrasound Findings

Prenatal Hydronephrosis.

Dilation of the fetal renal collecting system, prenatal hydronephrosis, is one of the most common abnormalities detection on prenatal ultrasonography, occurring in up to 5% of all pregnancies. Several grading systems have been developed in attempt to correlate prenatal and postnatal ultrasound findings with the ultimate urologic diagnosis. There are several grading systems ranging from descriptive to semiquantitative to quantitative. Most recently, a multidisciplinary consensus panel developed the Urinary Tract Dilation Classification System based on anterior posterior renal pelvic diameter, calyceal dilation, parenchymal thickness, and appearance of the ureter and bladder (Nguyen et al., 2014). However, each system has its limitations and none is uniformly used at this time.

The diagnosis of prenatal hydronephrosis may cause significant parental anxiety and physician uncertainty with regard to prenatal and postnatal management. Variations in the definition and management of prenatal hydronephrosis make accurate counseling regarding the risk of postnatal pathology challenging (Lee et al., 2006). Fetal hydronephrosis may develop secondary to transient dilation of the collecting system or congenital anomalies of the kidney and urinary tract (CAKUT). **Based on postnatal imaging studies, up to two-thirds of antenatal hydronephrosis is due to transient hydronephrosis. Of the remaining patients identified with CAKUT, UPJ obstruction was the most common diagnosis followed by VUR.** Other less common causes of prenatal hydronephrosis resulting from CAKUT include urethral obstruction (posterior urethral valves or urethral atresia), ureteral obstruction (ureterocele, obstructing megaureter), multicystic dysplastic kidney, prune-belly syndrome, hydrometrocolpos, and bladder agenesis.

Prenatal counseling based on ultrasonography findings is complex. It depends on comorbidities, the severity of hydronephrosis, (bi)laterality, involvement of the bladder suggestive of obstruction, and amniotic fluid volume because oligohydramnios occurs with severe renal disease. With rare exception, all fetuses with unilateral prenatal hydronephrosis and most with bilateral prenatal hydronephrosis may be managed expectantly. However, it is recommended that repeat prenatal imaging be performed and special consideration be given to fetuses with bilateral disease associated with oligohydramnios and features of renal dysplasia (Liu et al., 2014).

Postnatal management of these patients continues to evolve with aims to balance invasiveness, radiation, and cost of testing against the benefits of UTI prevention and resultant renal preservation. The Society for Fetal Urology 2010 recommendations propose obtaining postnatal ultrasonography before discharge after delivery in those with bilateral hydronephrosis and hydronephrosis in solitary kidneys or in patients with suspected bladder outlet obstruction, whereas evaluation can be delayed in those with unilateral hydronephrosis and a normal contralateral kidney (Nguyen et al., 2010). **The ultrasound should not be performed before the second day of life because of relative dehydration at birth, which leads to an underestimation of the level of hydronephrosis.** Should hydronephrosis remain moderate to severe bilaterally, a voiding cystourethrogram generally should be performed before discharge. Voiding cystourethrogram should also be performed to rule out VUR as the cause of dilation if megaureter is visualized.

Renal Cysts

Renal cysts encompass a broad spectrum of conditions in children. Many renal cystic diseases originate from genetic mutations at the level of the primary cilia (Avni and Hall, 2010). Cystic diseases of the kidney that are genetic include autosomal recessive polycystic kidney disease, autosomal dominant polycystic kidney disease, glomerulocystic kidney disease and nephronophthisis/medullary sponge kidney complex, cystic dysplasia, and medullary cystic dysplasia associated with syndromes. Nongenetic diseases include obstructive dysplasia, cystic dysplasia, simple cysts, multilocular cysts, cystic tumors, and cysts associated with chronic dialysis. The differential diagnosis of renal cystic disease is a difficult challenge that can be solved by a step-by-step approach using ultrasound imaging as well as family history and attention to specific clinical features.

Sonographically, it is important to characterize the renal cortex, medulla, and corticomedullary differentiation as well as the size, location, and number of cysts. Subcapsular cysts are seen in glomerulocystic disease; medullary cysts are seen in medullary cystic dysplasia and autosomal recessive polycystic kidney disease; diffuse cortical cysts are present in autosomal dominant polycystic kidney disease; and macrocysts in autosomal dominant polycystic kidney disease, tuberous sclerosis complex, and the TCF-2-mutation. Ultrasound is helpful not only in diagnosis of renal cysts but also for evaluation of hepatic involvement as well as for monitoring of complications such as hemorrhage and nephrolithiasis.

Multicystic dysplastic kidney is the most common cause of cystic disease in children (Cardona-Grau and Kogan, 2015). It is characterized by multiple noncommunicating cysts of varying sizes with no identifiable normal renal parenchyma. Although associated anomalies in the contralateral kidney are present in up to half of patients, use of voiding cystourethrogram or renal scintigraphy should be limited to abnormalities on renal ultrasound or the development of UTI. Similarly, there is no indication for performing serial ultrasound examinations, although the examiner may perform one additional ultrasound at 1 year to adequately evaluate the contralateral solitary kidney with any further follow-up imaging guided by any abnormality of the contralateral kidney, abnormal blood pressure, or enlarging multicystic dysplastic kidney.

Isolated renal cysts may also be incidentally detected. Although not validated in children, a modified Bosniak classification may be used as a guideline to direct the need for surgical intervention because of an increased risk of malignancy (Wallis et al., 2008). This should be differentiated from a calyceal diverticulum, which is a cystic cavity within the kidney that communicates with a calyx or, less commonly, with the renal pelvis through a narrow isthmus (Ochoa Santiago et al., 2018). Although a calyceal diverticulum is often misdiagnosed as a renal cyst, diagnosis is confirmed by the excretory phase of CT or MR urography. Calyceal diverticuli are usually asymptomatic; treatment is indicated if associated with pain or infection, abscess formation, urosepsis, or symptomatic calculus formation (Estrada et al., 2009).

Renal Tumors

Renal malignancies represent 6% of cancer diagnoses among children younger than 15 years of age (incidence 7.9 per million) in the United States (Ries et al., 1999)**. Wilms' tumor is the most common form of renal cancer in children younger than 15 years of age, representing approximately 95% of diagnoses.** Much less common were renal cell carcinomas (2.6% of renal cancers), clear cell sarcoma of the kidney (1.6% of renal cancers), and rhabdoid tumors of the kidney (1% of renal cancers).

Wilms tumor occurred most commonly among children younger than 5 years of age with a peak incidence in the first 2 years of life, whereas rhabdoid tumor of the kidney was diagnosed primarily in infants and clear cell sarcoma of the kidney was diagnosed primarily during the first 4 years of life. Renal carcinomas, by contrast, occurred with highest incidence among 15- to 19-year-olds.

Wilms tumor is primarily a sporadic disease, although approximately 10% occur in the context of a syndrome, including WAGR syndrome, Denys-Drash syndrome, familial Wilms tumor, Perlman syndrome, Fanconi

anemia, Beckwith-Wiedemann syndrome, and Simpson-Golabi-Behmel syndrome. Wilms tumor also occurs more frequently in isolated hemihypertrophy and Li-Fraumeni syndrome but less commonly than in the aforementioned syndromes (Scott et al., 2006). Thus patients with these syndromes require surveillance for Wilms tumor, which includes periodic, scheduled renal bladder ultrasound. Children most often have an asymptomatic abdominal mass, which is firm, nontender, and smooth but rarely crosses the midline on physical exam (Geller and Kochan, 2011). Given the association of Wilms tumor with the syndromes noted earlier, the exam should evaluate for associated anomalies, such as aniridia, hemihypertrophy, and other genitourinary anomalies. Abdominal ultrasonography is typically the initial study performed for evaluation of an abdominal mass with further evaluation with contrast-enhanced CT or MRI to characterize and stage the renal mass. Ultimately, the diagnosis is confirmed histologically. Further staging and treatment should be performed in a multidisciplinary fashion with pediatric oncology.

Although other renal tumors are significantly less common than Wilms, it is important they remain in the differential diagnosis of a child with a renal mass. Congenital mesoblastic nephroma is the most common renal tumor on antenatal ultrasound and in infants, with a mean age at diagnosis of 3.5 months. Complete surgical resection usually provides excellent outcomes (van den Heuvel-Eibrink et al., 2008). Neuroblastoma appears distinct on imaging given its nonrenal tissue, and these children typically have larger masses and may appear clinically ill. Rhabdoid tumors of the kidney often are seen after metastasis and occur in children less than 2 years of age; presentation with fever or hematuria is common. Clear cell sarcoma commonly metastasizes to the bone, and some variants can be challenging to differentiate from Wilms tumors. Finally, renal medullary carcinoma is seen almost exclusively in patients with sickle cell disease/trait.

Incidental Urolithiasis

As discussed earlier, 15% of pediatric patients with nephrolithiasis are diagnosed incidentally. **In asymptomatic patients, management depends on the size of the stone.** Ureteral and obstructing renal stones should be treated as discussed earlier. An asymptomatic, nonobstructing renal stone may be observed, although these patients should be seen regularly with routine surveillance ultrasonography to monitor for increase in size or number of stones, or silent obstruction per guidelines by the American Urologic Association (Assimos et al., 2016). These guidelines also recommend metabolic evaluation including a 24-hour urine collection in toilet-trained children or a “spot” urine sample to screen for hypercalciuria and other metabolic causes.

Key Points

- UTIs affect 3% of children yearly with the highest prevalence in female infants and boys younger than 1 year. Recurrent UTI occurs in up to 30%, more commonly in those with VUR and BBD.
- Management of VUR remains controversial and aims to prevent recurrent febrile UTIs and renal injury and to minimize the morbidity of treatment and follow-up.
- BBD includes lower urinary tract dysfunction and bowel dysfunction. A thorough history from the caretaker and child is required to guide therapy.
- Pediatric nephrolithiasis is rising in incidence. Imaging must minimize radiation as children are at increased risk from exposure and have longer follow-up times given longer life expectancies.
- Prenatal hydronephrosis is due to transient collecting system dilation or CAKUT. Counseling depends on comorbidities, severity, (bi)laterality, bladder involvement, and amniotic fluid volume.

Pediatric Urogenital Imaging

Hans G. Pohl MD, FAAP

Imaging has long been a critical component in urologic investigation and diagnosis for both adults and children. However, studies that are routine and tolerable in adults may require anesthesia or specially trained technicians in children. Doses may need to be adjusted, and equipment may need to be available that is suitable for the smaller patient. The urologist treating children needs to be aware of these age-specific differences for the purposes of ordering and interpreting these tests.

Having decided that imaging of the urinary tract is appropriate, the clinician should weigh the doses of radiation given per study, whether interval follow-up would be necessary (thus presenting additional radiation exposure), the need for contrast agents, and the need for anesthesia/sedation to obtain adequate images against the anticipated clinical benefit. Although quantifying the radiation risk accurately for the individual patient is challenging, there is consensus that we should practice under the “as low as reasonably achievable” (ALARA) principle (Don et al., 2013; ICRP et al., 2013). As it is not currently possible to predict an individual's susceptibility to radiation effects, all patients should be treated as radiation sensitive (Kleinerman, 2009). The risks associated with radiation are touched on only briefly here, as this is discussed in more depth in Chapter 2.

Efforts to establish appropriate criteria for the selection of imaging modalities to evaluate the urinary tract in children have resulted in guidelines from a variety of professional organizations, such as the American Academy of Pediatrics (AAP), National Institute for Health and Care Excellence (NICE), Italian Society of Pediatric Nephrology, Canadian Pediatric Society (CPS), Polish Society of Pediatric Nephrology (PSPN), and European Association of Urology (EAU)/European Society for Pediatric Urology (ESPU) (Ammenti et al., 2012; Mori et al., 2007; Polish Society of Pediatric Nephrology, 2015; Roberts, et al., 2011; Robinson et al., 2014; Stein et al., 2015). Motivated by an interest in reducing unnecessary invasive testing, each guideline is based on the best available data at the time and expert opinion. Most recently, the American College of Radiology established a series of guidelines called the ACR Appropriateness Criteria, Hematuria-Child (2018) and Urinary Tract Infection-Child (2016), which seek to balance the relative radiation exposure from imaging against the diagnostic information yielded based on the prevalence of findings in specific clinical scenarios (Expert Panel on Pediatric Imaging, 2017).

This chapter describes the assets and liabilities of the imaging modalities employed in the evaluation of the pediatric urogenital system, organizing the discussion by nonionizing versus ionizing tests first and then describing what information can be gleaned by use of each modality at varying levels of the urinary tract as follows: (1) kidney and ureter, (2) bladder and urethra, and (3) scrotum, testes, and internal genitalia. At each level of the urinary tract, topics are organized by common reasons for evaluation as follows: (1) obstruction, (2) cysts and masses, (3) infection, (4) other congenital malformations not elsewhere covered, and (5) trauma.

Technique

Nonionizing

One form of nonionizing radiation, sonography is the archetype minimally invasive study that provides rationale for its widespread use. However, the same cannot be said about magnetic resonance imaging (MRI) because many children require sedation or anesthesia because of longer acquisition times (Arthurs et al., 2012). This risk associated with sedation or anesthesia is typically higher than the risk for nephrogenic systemic fibrosis (NSF) secondary to the use of gadolinium in a child with poor renal function or in the setting of immature renal function in a neonate, or even of iodinated-contrast nephropathy in children with poor renal function (Karcaaltincaba et al., 2009; Thomsen, 2007; Thomsen et al., 2007). Both contrast materials pose a higher risk for allergic reaction although still quite small (Arthurs and Bjørkum, 2013). The radiofrequency pulses creating the electromagnetic field can cause patient heating that must be monitored to prevent hyperthermia, which has been reported, though rarely (Kussman et al., 2004; Wang et al., 2007). The long-term safety of magnetic resonance (MR) exposure has been questioned based on revealed changes in gene expression related to magnetic field exposure (Bonassi et al., 2007; Kimura et al., 2008; Simi et al., 2008). Regardless, no human data have thus been produced, but there is recommendation to avoid fetal MR in the first trimester. Sonography has not shown to cause gene expression changes and is regarded as safe at all ages.

Key Point: Nonionizing Technique

- Contrast-enhanced sonography and machine learning–enhanced analysis of sonographic images should be considered as these tools become increasingly available, because they may obviate the need for more invasive testing.

Ionizing

Ionizing radiation is considered more harmful in children than in adults because of the greater radiosensitivity of developing tissues and potential for higher cumulative doses over the child's lifetime (Arthurs and Bjørkum, 2013). Thus, in children, the stochastic effects of repeated exposure (i.e., internal cell injury) can result in radiation-induced malignancies after a prolonged latent period. When evaluating the literature on ionizing radiation risk, care must be taken to determine if the risk reported is estimated, modeled, or measured from clinical practice. Variations in technique, patient age, size, and varied intervening studies during the long study intervals required can make measured studies difficult to interpret. Acknowledging these significant limitations in determining ionizing radiation risks in children, there appears to be reasonable evidence to suggest a dose-related risk in children and even in utero (Arthurs and Bjørkum, 2013). There is considerable work being done to reduce radiation doses of individual tests while still maintaining the necessary diagnostic accuracy to provide good care. Likewise, better medical decision making and offering nonionizing alternatives have gained momentum.

Key Point: Ionizing Technique

- The ALARA principle should be followed when considering imaging in children.

sonography

Fundamentals of Sonography in the Fetus and Child

A variety of urologic conditions can be diagnosed with near certainty prenatally using sonography to investigate the presence and quality of the renal cortex, the laterality of the abnormality, the position of the kidney(s) within the abdomen and association with other organs, and finally the presence of a normal amount of amniotic fluid and/or urine within the bladder (Dias et al., 2014).

Amniotic fluid is primarily a dialysate of fetal blood across the permeable fetal skin before 8 to 10 weeks. Early fetal urine production begins around 10 to 12 weeks, such that by 20 weeks, sonography can detect the majority of urologic abnormalities.

The features of a normal urinary tract include two kidneys, one on each side located in the renal fossa, with a renal cortex that is isoechoic or slightly hypoechoic to the liver, the presence of discrete interfaces between the cortex and the medulla, the absence of cortical cysts, and the absence of masses or dilation of the collecting system or bladder.

Because a bladder should be visualized in all fetuses by 10 to 12 weeks' gestation, bladder cycling might be observed if patience is exercised (Yiee and Wilcox, 2008). The normal bladder cycles regularly; however, the fetal bladder is never completely empty and always contains a small residual volume of urine. Lastly, attention should be placed on the placement of the umbilical cord and completeness of the anterior abdominal wall because these are highly associated with exstrophy and cloacal exstrophy.

It is important to recognize the subtle differences in the sonographic appearance of the newborn kidney in comparison to older children and adults. The distinct corticomedullary differentiation combined with a slightly hyperechoic renal parenchyma compared with a mature kidney can be mistaken for hydronephrosis in a newborn (Fig. 24.1) Also, the degree of hydronephrosis can be underestimated in an early postnatal sonogram (i.e., up to 2 days after birth) and/or in the setting of dehydration.

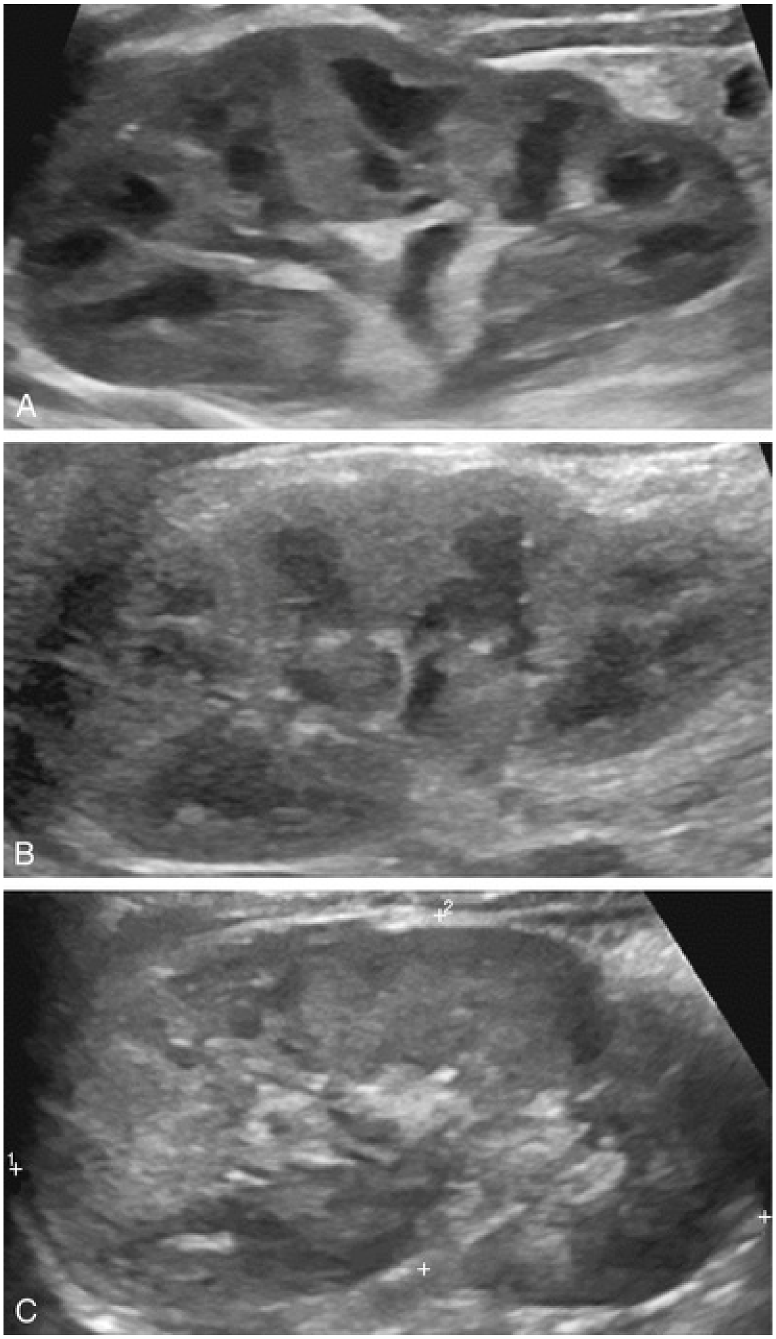

FIG. 24.1 (A and B) Postnatal sonograms demonstrating the high contrast cortico-medullary differentiation typical of the newborn kidney, which might be mistaken for dilated calyces. (C) For comparison, a renal sonogram in the older child.

Unfortunately, prenatal sonography does have a few limitations such as low amniotic fluid volume, maternal body habitus, maternal bowel gas, maternal pelvic bony structures, or fetal position. In these respects, MRI is a superior modality.

Kidney/Ureter

Obstruction

Hydronephrosis Versus Cystic Renal Diseases.

Dilation of the renal collecting system and parenchymal cysts are the most common findings on prenatal sonography (Blyth et al., 1993). A differential diagnosis list that considers most possibilities would include hydronephrosis (obstructive and nonobstructive), multicystic dysplastic kidney, polycystic kidney disease (autosomal recessive and autosomal dominant), and cystic nephroma.

Many parameters have been proposed for standardization of hydronephrosis reporting, but variation among specialties persists (Zanetta et al., 2012). The Society for Fetal Urology classification system is the most widely used by pediatric urologists and is based on the extent of calyceal dilation, involvement of minor calyces, and parenchymal thinning (Nguyen et al., 2010) (Fig. 24.2). Others use a measure of renal pelvic anteroposterior diameter or a combination of classification systems to aid in decision making and risk stratification (Timberlake and Herndon, 2013). These inconsistencies in hydronephrosis reporting make it paramount that the clinician review the actual images when making clinical decisions.

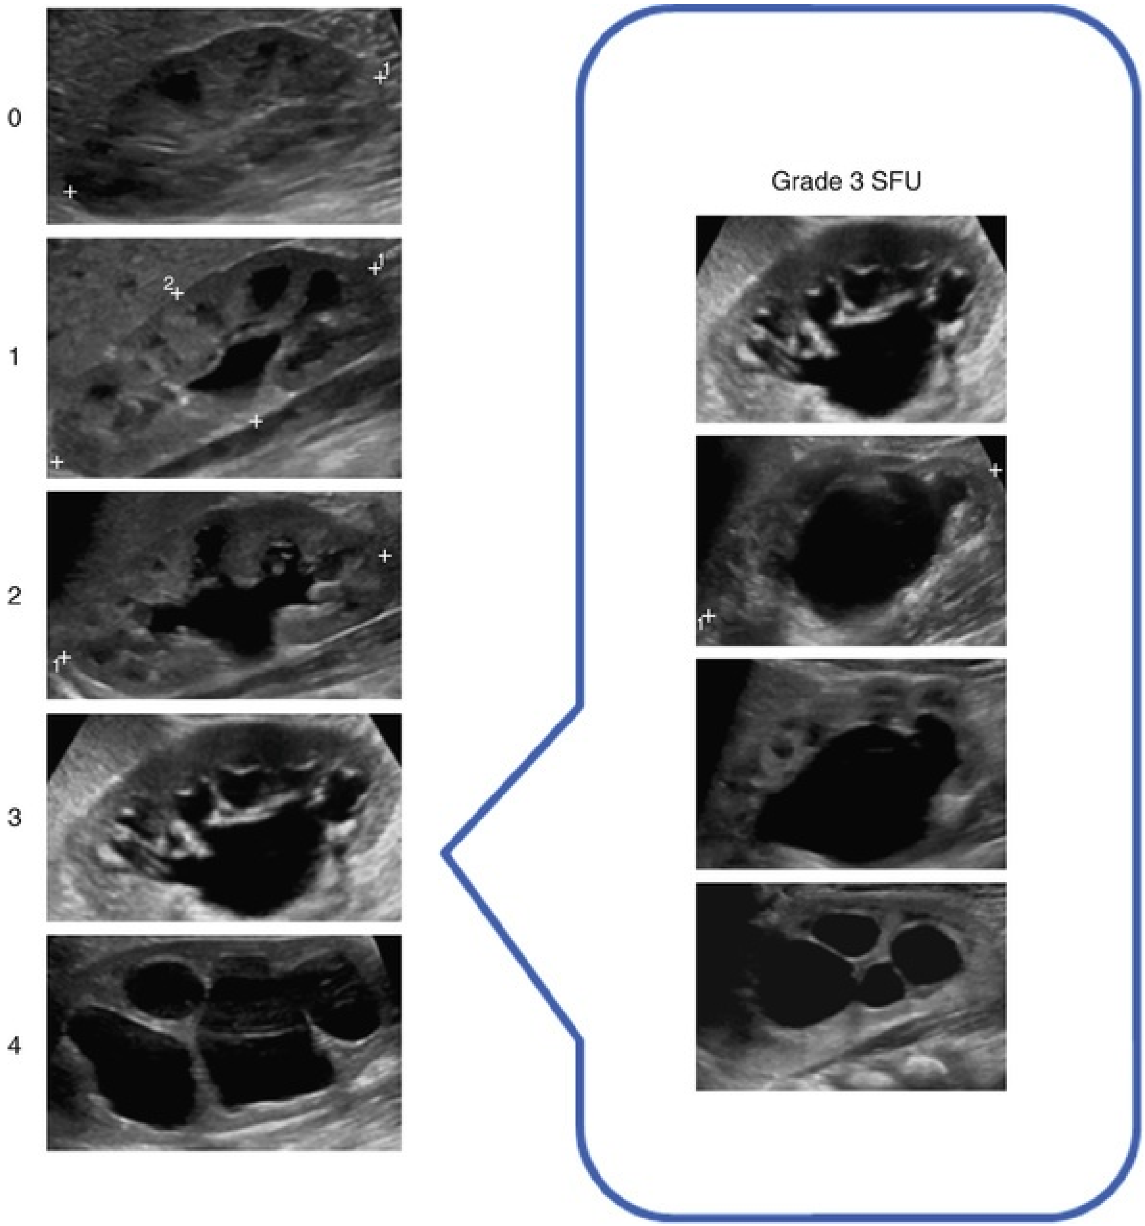

FIG. 24.2 The Society for Fetal Urology *(SFU)* criteria as demonstrated in postnatal sonograms. Grade 0 shows no central renal dilation. In grade 1, the renal pelvis only is visible; in grade 2, major calices can be identified; in grade 3, major and minor calices can be identified; and grade 4 has features of grade 3 but with parenchymal thinning as well. Within grade 3, there are many different degrees of collecting system dilation that conform to the criteria.

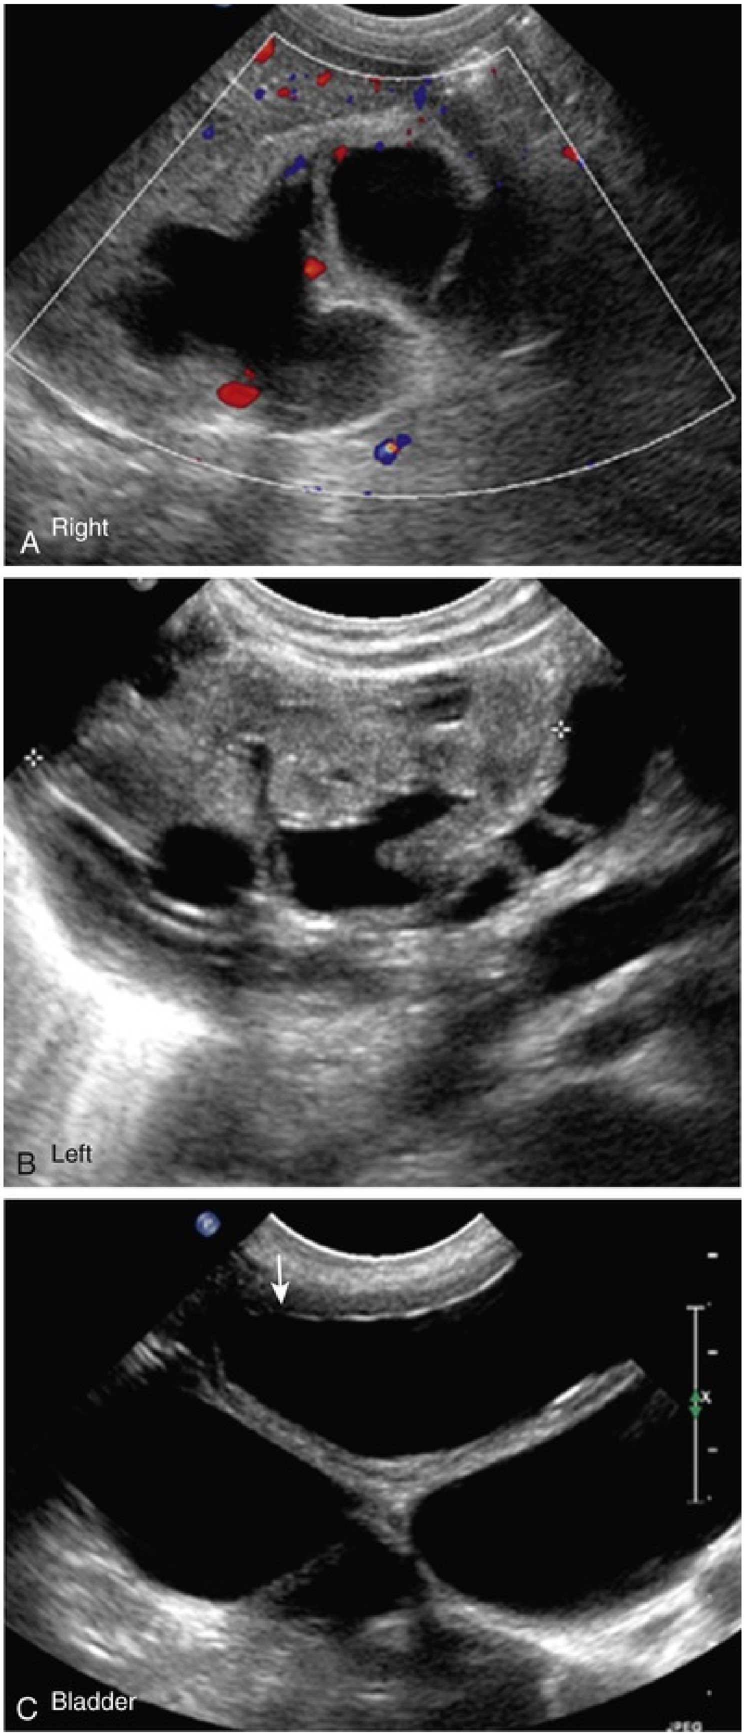
Although it has been debated that all cases of hydronephrosis represent obstruction in some form or another, the majority of hydronephrosis follows a benign natural history, such that improvement or resolution is seen. More profound developmental abnormalities present as moderate to severe hydronephrosis because of high-grade obstruction, and the transition between dilated and nondilated urinary tract localizes the site of obstruction to the ureteropelvic junction, ureterovesical junction, or urethra.

Dilated Ureters.

Generally considered a hallmark of obstruction, ureteral dilation may also occur in the absence of it, such as when it represents vesicoureteral reflux (VUR). Certain entities, such as megaureter and ureterocele, include both obstructive and nonobstructive variants that can be further evaluated using a functional test for urine drainage, typically diuresis renography or magnetic resonance urography (MRU).

Functional Interpretation of Sonography of the Kidney.

Although standard renal sonography is an anatomic study, inference of function has been proposed using a variety of techniques and measurements (Grenier et al., 2013; Inchingolo et al., 2013; Peters et al., 2013). The main clinical question in the setting of hydronephrosis is whether it is caused by obstruction, VUR, or neither as a normal variant. Hydronephrosis secondary to obstruction can be more fully evaluated using functional imaging. Hydronephrosis secondary to VUR is discussed later in this chapter. In the setting of bilateral hydroureteronephrosis, a thickened bladder, and poor emptying, voiding cystourethrography (VCUG) should be performed to rule out a posterior urethral valve (Fig. 24.3). Otherwise, diuretic renography is the gold standard. There are promising advancements using computer-aided shape analysis and ultrasound elastography to measure the dilated collecting system and renal parenchymal or pelvic tension as an indirect measure of obstruction (Cerrolaza et al., 2016; Grenier et al., 2013; Kang et al., 2013; Peters et al., 2013). If these sonographic techniques prove accurate in assessing function, then other ionizing techniques could be reduced dramatically or even avoided.



A Right
B Left
C Bladder
x
JPEG

FIG. 24.3 Sonographic example of an infant found to have posterior urethral valve. Images of the kidneys (A and B) demonstrate echogenic renal parenchyma, moderate to severe hydronephrosis, and renal cortical cyst (upper pole left kidney). The image of the bladder (C) demonstrates significant distal hydroureter bilaterally.

Key Points: Obstruction

- Sonography is the initial examination to perform for suspect obstruction, as well as being helpful for longitudinal follow-up.
- Based on the sonographic findings, ancillary imaging (e.g., VCUG and/or diuresis renography) might be considered.
- A normal infant renal sonogram can be confused with mature hydronephrosis because of hypoechoic renal pyramids with a distinct corticomedullary junction.
- Diagnosis of obstruction in children with diuresis renography requires a review of all parameters of the test because variations in technique can skew results considerably.

Cysts/Masses/Stones

Renal Cysts.

Cystic disease can mimic hydronephrosis on initial inspection but can be discriminated from it ultimately because cysts do not communicate with one another such as dilated calyces and pelvis do. In the case of multicystic dysplastic kidney (MCDK), the cysts are of varying sizes and randomly distributed throughout the renal parenchyma; in addition, they do not communicating with each other and are unilateral (Fig. 24.4A). By contrast, bilateral cystic lesions should raise concern for polycystic kidney disease of which two types are seen: autosomal recessive polycystic kidney disease (ARPKD) and autosomal dominant polycystic kidney disease (ADPKD). ARPKD is characterized by enlarged and homogeneously hyperechoic parenchyma that results from dilation of the collecting tubules (see Fig. 24.4B). ADPKD is identified by the presence of enlarged kidneys where the parenchyma is almost replaced by cysts. A multilocular cystic nephroma is a benign cystic renal tumor that shares features with MCDK and cystic Wilms tumor. It, too, presents as noncommunicating cysts of varying sizes, but generally has more parenchymal tissue than MCDK. Multilocular cystic nephroma is a tumor of infancy, whereas (cystic) Wilms tumor occurs in children at around 2 to 4 years of age.

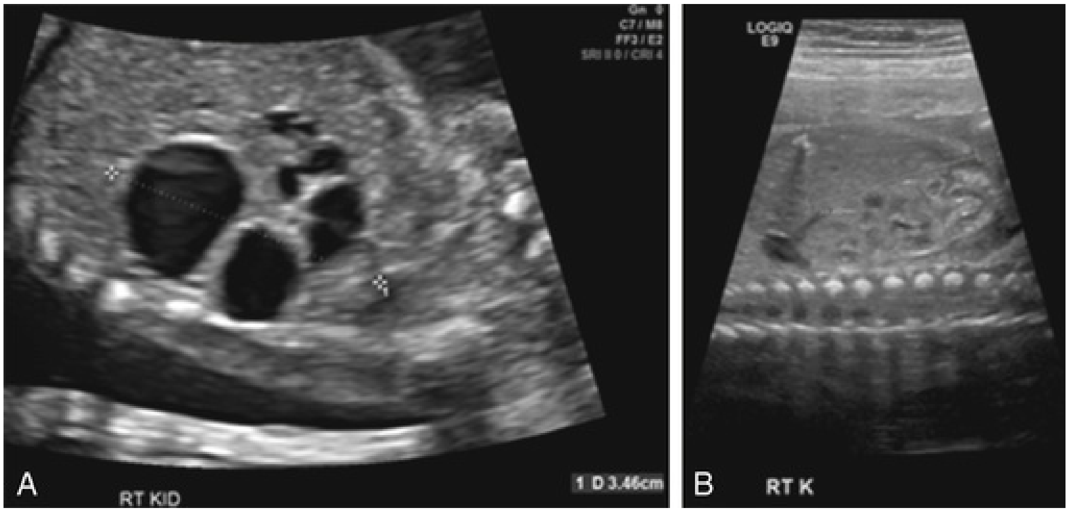


FIG. 24.4 (A) Prenatal sonogram demonstrating randomly distributed cortical cysts typically seen in multicystic dysplastic kidneys. (B) Prenatal sonogram demonstrating homogeneously hyperechogenic renal parenchyma of autosomal recessive polycystic kidney disease.

Renal/Abdominal Solid Masses.

A differential diagnosis list that considers most possibilities would include: neuroblastoma, congenital mesoblastic nephroma, Wilms tumor, renal vein thrombosis, renal artery thrombosis, adrenal hemorrhage, and rare renal solid tumors (rhabdoid, clear cell, angiomyolipoma) (Fig. 24.5). In most cases, hallmark features on sonography in the context of patient age and presenting symptoms and signs suggests the diagnosis; however, additional imaging with contrast-enhanced computed tomography (CT) is commonly performed.

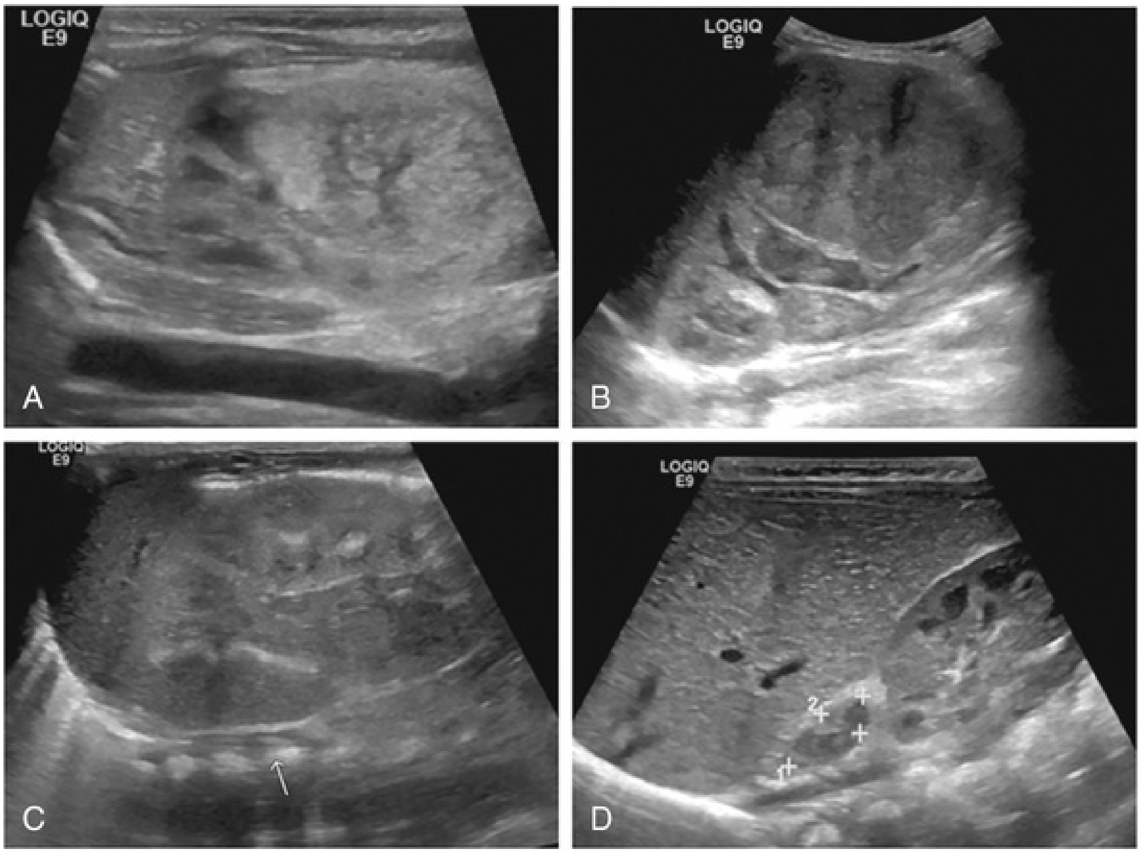

FIG. 24.5 Four sonographic examples of renal “enlargement” in which the diagnosis is suggested by the clinical presentation. (A) A 1-month-old male infant with a prenatally detected renal mass that was confirmed to be a congenital mesoblastic nephroma after nephrectomy. (B) A 17-month-old male patient with a right lower pole renal mass detected on physical examination and found to be Wilms tumor; (C) A 4-day-old female infant with acute kidney injury and hypertension with diffuse left renal enlargement diagnosed as renal vein thrombosis. (D) A 1-week-old female infant with prenatal diagnosis of a suprarenal mass consistent with adrenal hemorrhage.

Renal Stones.

Children with stone disease will likely have a lifetime of screening and point-of-care imaging, so an effort to minimize the amount of radiation is needed. The parent and older child should be well-informed of these intentions so as to play an active role in this plan, especially if visiting an unfamiliar emergency facility or physician. Sonography might be sufficient as an initial screening test or follow-up imaging in most children with acute renal colic from stones, as opposed to reflexively obtaining a CT scan or a kidney, ureter, and bladder (KUB) test. Sonography is ideal at detecting hydronephrosis and hydroureter, which can direct further imaging if the calculi cannot be definitively identified. It also can reliably detect intraparenchymal calculi and nephrocalcinosis (Fig. 24.6A). On sonography, calculi appear echogenic with shadowing, not to be confused with peripelvic fat, which is echogenic without shadowing. A "twinkling" artifact can also be seen when using color Doppler to distinguish calculi from other hyperechoic signals (Lee et al., 2001; Lu et al., 2013) (see Fig. 24.6B).

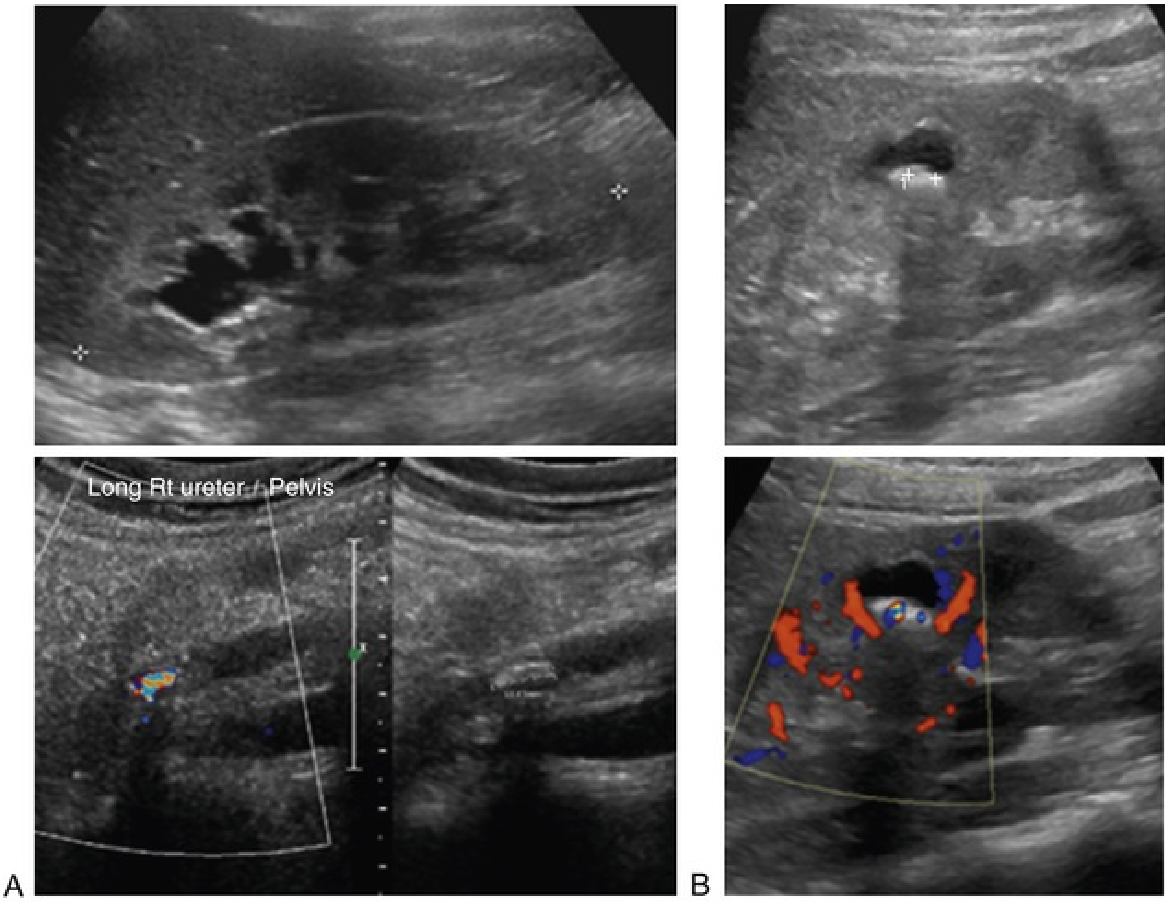

FIG. 24.6 (A) Renal sonogram demonstrating hydronephrosis and hydroureter associated with a mid-ureteral calculus. (B) "Twinkling" artifact seen by color Doppler application to a renal calculus.

Ureteral Stones.

Ureteral stones may present with or without dilated ureter above the stone, depending on the degree to which the stone obstructs urine flow. Unlike adults, ureteral stones in the distal/pelvic ureter are more easily imaged in children because of the shorter distance to the stone. The “twinkling” artifact is also seen in ureteral stones.

Key Points: Cysts/Masses/Stones

- Sonographically, MCDK is characterized by echolucent spaces (cysts) of varying sizes that are randomly distributed throughout the kidney with a paucity of renal parenchyma that is hyperechoic.
- ARPKD typically affects both kidneys and is characterized by enlarged and echogenic parenchyma.
- ADPKD typically affects both kidneys and is characterized by replacement of the renal parenchyma by cysts.
- Although patient age and hallmark sonographic features suggest the diagnosis of renal masses, contrast-enhanced CT of the abdomen should follow.

Infection

Sonography in the setting of UTI is typically used as an initial screening test to rule out obvious anatomic abnormalities that may warrant further investigation. Despite that it is not routinely employed during the onset of treatment for UTI, sonography should be employed when the patient fails to improve or worsens despite appropriate antibiotic treatment.

Sonography has been found to be very sensitive for the detection of *significant* renal abnormalities, but much less so for uncomplicated VUR, duplication anomalies, acute pyelonephritis, and focal renal scarring (Horgan et al., 1984; Jequier et al., 1985; Kangarloo et al., 1985; Leonidas et al., 1985). Alone it is rarely useful for most cases of nonfebrile and febrile UTI, so it is often used in complement with VCUG when there is suspicion for a urologic abnormality. Most imaging algorithms are applied after treatment and in the interest of identifying risk factors for recurrent UTIs, and anatomic abnormalities that increase the risk for complicated UTIs and associated renal injury. For patients requiring hospitalization, it is often advocated that screening sonography be obtained before discharge to exclude obstruction. Otherwise, imaging is delayed until after discharge.

In the absence of VUR, hydronephrosis revealed by sonography can be further evaluated by diuresis renography, which in combination, reliably localizes the site of obstruction in all cases (O'Hara, 2002; Shalaby-Rana et al., 1997). Despite its many advantages, standard gray-scale sonography is inferior in the detection of acute pyelonephritis or renal scarring in comparison to technetium-99m dimercaptosuccinic acid (^{99m}Tc-DMSA). A normal sonogram is not sufficient to risk-stratify a child with acute pyelonephritis or a good predictor of the presence of VUR (Nelson et al., 2014). Advances to improve sonographic accuracy in detection of acute pyelonephritis are promising (McArthur and Baxter, 2012).

Contrast-enhanced and noncontrast voiding sonography is proving its accuracy for detection of VUR, but the technique is still in its infancy and not yet widely performed (Darge, 2010; Fallah et al., 2012; Papadopoulou et al., 2009). It uses the detection of echogenic microbubbles tracked in real time during voiding and bladder cycling. A 5-point grading system has been developed similar to that used for VCUG (Darge and Troeger, 2002). It is associated with a higher cost because of time consumption, but certainly promising as a nonionizing detection and monitoring option for VUR (Piscitelli et al., 2008).

Key Points: Infection

- Numerous guidelines have been published on the radiographic evaluation after pediatric urinary tract infection and sonography is employed as an initial screening modality despite its low yield.
- A normal sonogram is insufficient to risk stratify a child with a febrile UTI and is not a good predictor for VUR.
- The “bottom-up” approach relies on VCUG—after sonography—to identify all cases of VUR that may result in overtreatment of low-grade VUR.
- The “top-down” approach replaces screening sonography with a DMSA renal scan to identify acute pyelonephritis and/or renal scarring. Proponents of this algorithm recommend VCUG only in response to abnormal DMSA scans as an indicator of high-risk patients.

Other Congenital Malformations

Sonography is the initial means to evaluate any congenital anomaly of the upper urinary tract for the various reasons already mentioned. In addition, sonography is the initial imaging evaluation for infants with suspected differences of sexual development to identify the presence and relationship between Müllerian structures and the urinary tract.

Trauma

Sonography has been shown to be useful to evaluate the pediatric trauma patient in the acute setting, where it compares favorably to contrast-enhanced CT for the initial evaluation of renal injuries (Amerstorfer et al., 2015). More recently, contrast-enhanced sonography has been demonstrated to be as sensitive as contrast-enhanced CT for the evaluation of pediatric blunt abdominal trauma (Miele et al., 2016).

Key Points: Trauma

- Abdominal sonography is useful as part of the acute trauma evaluation and compares favorably to contrast-enhanced CT. Sonography should be considered for the longitudinal evaluation of known renal injuries, particularly to assess resolution of perinephric hematomas or urinomas.
- Ionizing radiation is used to evaluate genitourinary trauma, frequently with the addition of intravenous or intraluminal iodinated contrast.
- Radiographic evaluation is deemed complete only when delayed views of the renal parenchyma and collecting system are obtained on CT, or when lateral projections of the bladdder, bladder neck, and urethra are obtained on cystourethrography.

Bladder/Urethra

Obstruction

Bladder sonography can be performed to assess both anatomy and basic function. From an anatomic standpoint, sonography can be used to detect ureteroceles, large diverticula, bladder calculi, bladder debris, or suspicious bladder masses (Fig. 24.7) Bladder wall thickness is a more difficult proposition because it changes significantly with bladder volume and age. Many have tried to standardize measurements of the bladder wall and index this to volume to predict pathology or define normality, but this has not gained widespread use because of its complexity and variability (Bright et al., 2010; Kaefer et al., 1997; Yeung et al., 2004). Regardless, a grossly thickened bladder on sonography should be viewed with suspicion if the clinical picture is consistent with voiding dysfunction (Yeung et al., 2007). Simple functional assessment of bladder emptying can be quantified by calculating prevoid and postvoid volumes. For example, a thickened bladder and dilated posterior urethra known as the “keyhole sign” is highly suggestive of a posterior urethral valve (Fig. 24.8).

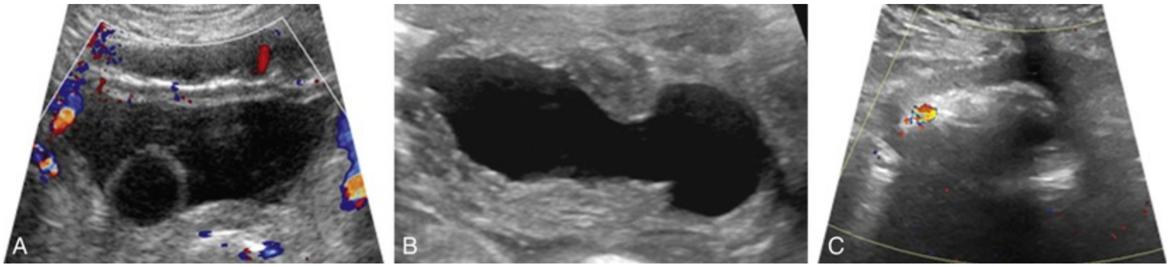

FIG. 24.7 Sonographic images of the bladder reveal ureterocele (A), diverticulum (B), and large calculi with “twinkling” artifact (C).

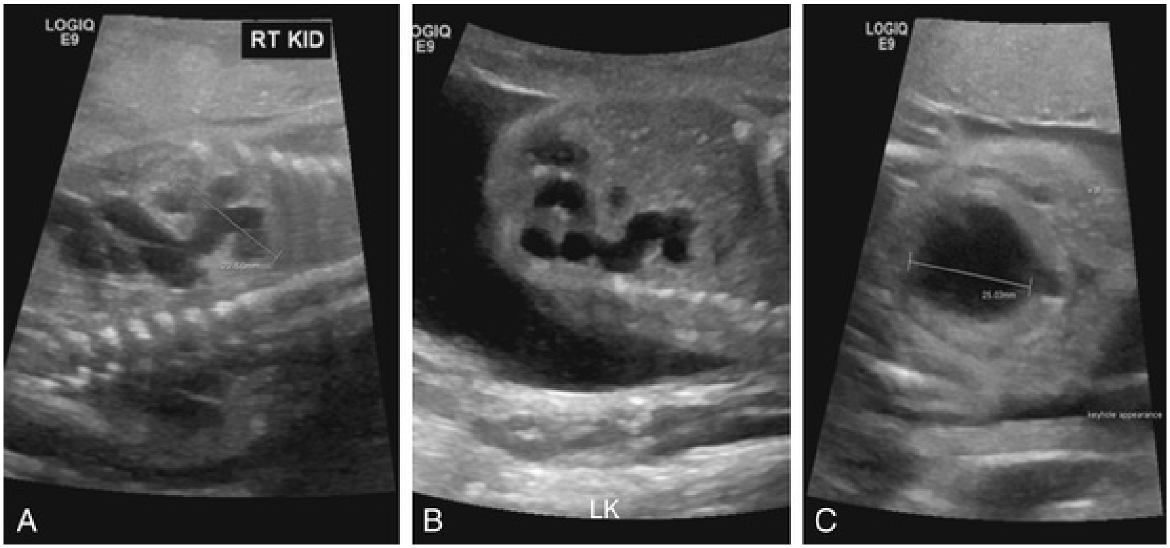

FIG. 24.8 Prenatal sonogram demonstrating bilateral hydronephrosis and hydroureter (A and B) and the thickened bladder and “keyhole” sign (C) typically associated with bladder outlet obstruction, in this case of posterior urethral valve.

Cysts/Masses

Midline Pelvic Cysts.

A differential diagnosis list that considers most possibilities would include: hydrometrocolpos (urogenital sinus anomalies), ovarian cyst, distended bladder, and urinary ascites. Hydrometrocolpos is distension of the uterus and vagina with mucus or blood, and results from vaginal obstruction secondary to imperforate hymen, vaginal atresia, transverse vaginal septum, or from retrograde flow of urine in urogenital sinus and cloacal malformations (Banerjee et al., 1992; Hill and Hirsch, 1985) (Fig. 24.9).

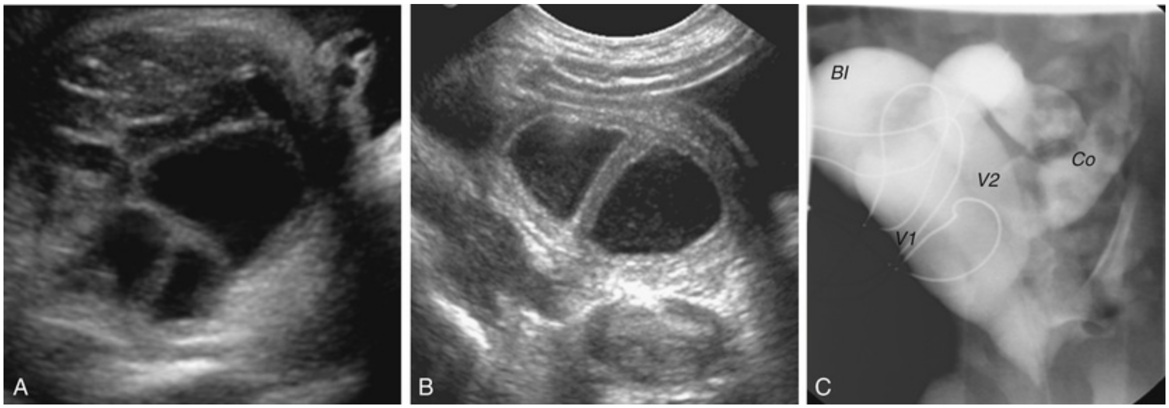

FIG. 24.9 (A) Prenatal sonogram performed for oligohydramnios in a 34-week female fetus demonstrating dual pelvic cystic structures below a dilated bladder. (B) Postnatal sonography confirms the pelvic structures to be hemivaginas. (C) Cystogram confirms the diagnosis of cloacal anomaly because the hemivaginas, dilated bladder, and distal colon are opacified with contrast medium injected into a single perineal opening. *Bl,* Bladder; *Co,* colon; *V1,* hemivagina; *V2,* hemivagina.

Bladder Tumors.

To properly assess the contents of the bladder and the bladder wall, it is important that the bladder be as full as possible, particularly if there is concern for a bladder mass. Bladder masses are well delineated by sonography and include: clot, benign and malignant tumors, foreign bodies, and pseudotumors. Children with gross hematuria might have intravesical clots easily distinguished from bladder tumors by imaging the patient supine and prone. A clot will be seen to move about the bladder, but a tumor will remain fixed. Tumors of the bladder wall can arise from the urothelium, mesenchyme, neuroendocrine cells, or in response to viral infection. Unfortunately sonography does not easily discriminate between histologic types, and further clinical assessment is indicated.

Infection

Aside from using sonography to evaluate urinary tract infections as a whole, viral cystitis can also be confirmed sonographically based on the presence of a thickened bladder wall, at times severe enough to be mistaken for a bladder mass. Typically, these patients present with a prodrome viral upper respiratory tract illness, gross total hematuria, and significant urgency and frequency of urination.

Other Congenital Malformations

Abdominal Wall Defects.

Though generally quite rare, bladder exstrophy and prune belly syndrome represent defects in formation of the abdominal wall with associated urogenital abnormalities. Classic bladder exstrophy can be identified prenatally when the bladder is not visualized, the lower abdominal wall is irregular, and the umbilicus is inferiorly placed. Prune belly syndrome is suggested by observing hydronephrosis/hydroureter, a distended bladder, and the absence of testes in the scrotum in a male fetus either prenatally or after birth (Fig. 24.10).

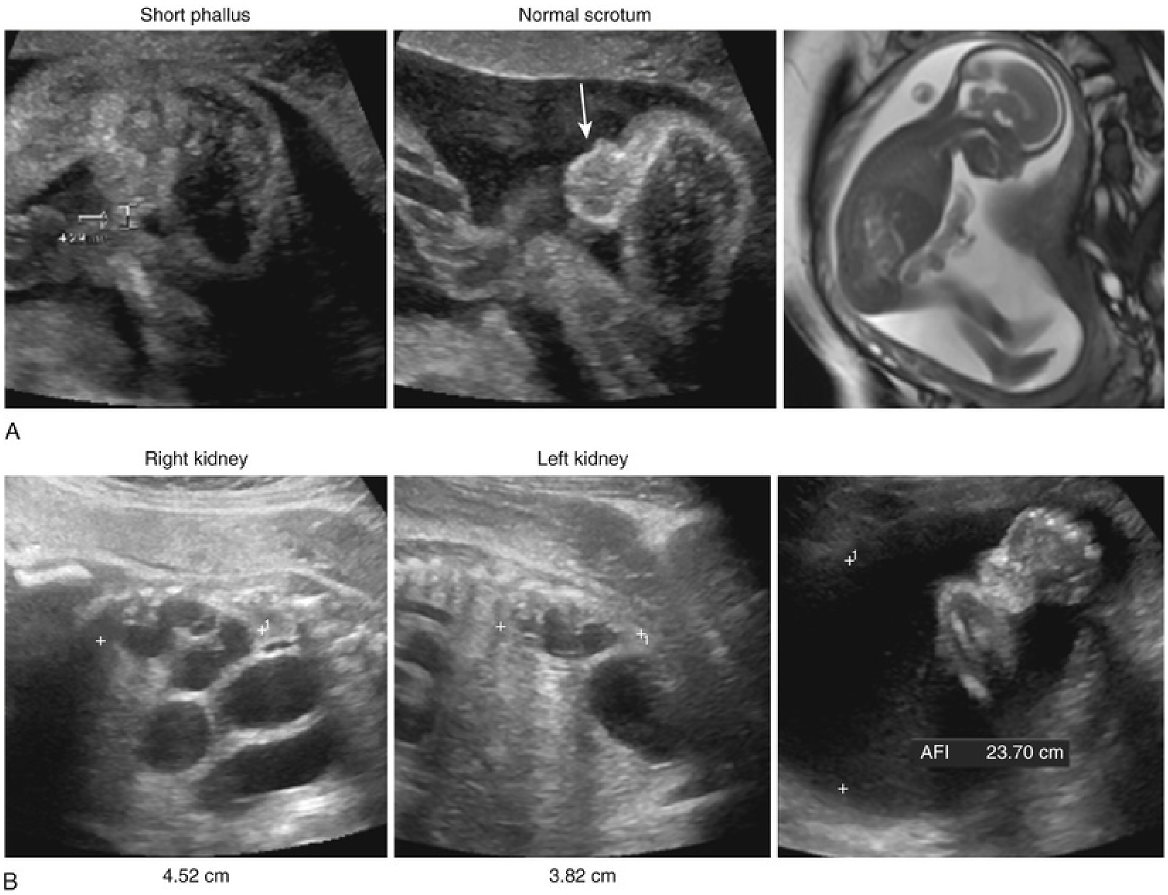

FIG. 24.10 (A) Prenatal sonogram and magnetic resonance image of a male fetus with classic bladder exstrophy. The kidneys were normal, and no hydroureter was seen, but the cord inserted low into the abdomen, the bladder was not visualized in pelvic views, and the phallus was short. (B) Prenatal sonogram of a male fetus with prune-belly syndrome demonstrating the presence of a high amniotic fluid index *(AFI).* Although prune-belly syndrome and posterior urethral valve share sonographic features, such as hydronephrosis and hydroureter, this case did not demonstrate a thickened bladder wall and distinct “keyhole” sign, which are typical of posterior urethral valve. Also, the testes were not seen in the scrotum, which is another prenatal clue that the diagnosis was prune-belly syndrome.

Trauma

Scrotum/Testes/Internal Genitalia

Acute Scrotum.

Genital imaging is limited to essentially four basic conditions: the acute or enlarged scrotum, testicular/paratesticular masses, cryptorchidism, and ambiguous genitalia. Sonography is always the initial and usually the only imaging modality needed. Overuse of sonography for scrotal concerns is widespread as most scrotal concerns can be diagnosed on the basis of history and physical examination rather than imaging. Likewise, overzealous interpretation of scrotal imaging especially in contradiction to the clinician's physical examination should be avoided.

In the acute scrotum, color Doppler sonography can be useful in differentiation of the child with an equivocal clinical examination for torsion (Baker et al., 2000; DaJusta et al., 2013). Surgical exploration should not be delayed if torsion is suspected and the delay to image will compromise salvageability. Because of reported false-negative results using color Doppler sonography, investigators have used high-resolution sonography to image torsion of the spermatic cord itself known as the “whirlpool sign.” (Fig. 24.11) (Vijayaraghavan, 2006). This was shown to increase sensitivity to 96% (from 76% using color Doppler sonography) and 99% specificity (Bandarkar and Blask, 2018; Kalfa et al., 2007). Salvageability of the testicle based on sonographic appearance is difficult to predict except in the setting of no arterial flow and parenchymal heterogeneity, in which case 100% were nonviable at exploration (Kaye et al., 2008).

LT VARICOCELE

FIG. 24.11 Scrotal sonogram in a 19-year-old male patient with acute onset of right testis pain. Doppler sonography (A) shows the “whirlpool” sign, which has been associated with torsion of the spermatic cord. Doppler sonography did not identify flow, as compared with the left testis (B), which demonstrated ample flow in the nontorsed cord and testis. An

incidental left varicocele was noted as well.

Other nontorsion scrotal events can be seen with color Doppler sonography. Epididymo-orchitis can be visualized as hyperemia of the epididymis and/or testicle (Fig. 24.12). However, this must be correlated with the clinical presentation as this can also be seen in the setting of recent spontaneous detorsion. Torsion of a testicular or epididymal appendage can also be captured by a skilled technician as an upper pole/epididymal hypoechoic/avascular nodule with surrounding hyperemia. Acute idiopathic scrotal edema can be identified by the “fountain sign” or hyperemia of a thickened scrotal wall in the absence of any of the previously mentioned diagnoses (Geiger et al., 2010).

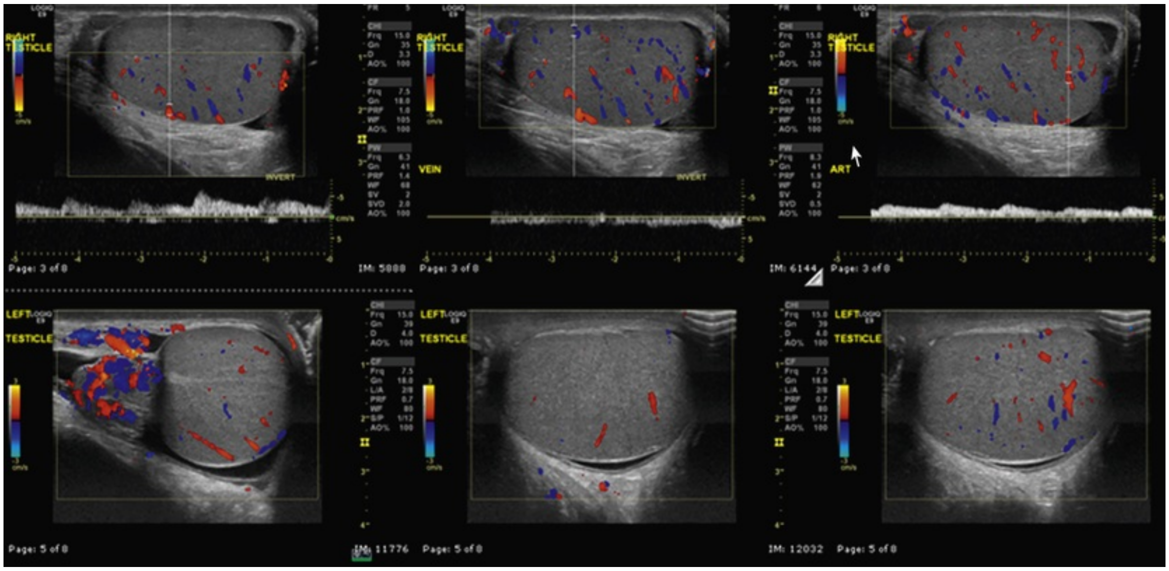

FIG. 24.12 Scrotal sonogram in a 13-year-old male patient with acute onset of left scrotal swelling showing hyperemia of the left epididymis consistent with epididymo-orchitis.

Key Points: Acute Scrotum

- In addition to careful history and physical examination, scrotal sonography provides much of the information needed to discriminate between inflammation, neoplasm, trauma, and testicular torsion.
- Nuclear scintigraphy may be used to evaluate testicular torsion but provides little additional information over what can be gleaned from sonography.

Cysts/Masses

Pediatric testicular and paratesticular masses must be viewed in conjunction with the patient's age and complete clinical picture but are generally well characterized by sonography (Delaney and Karmazyn, 2013). The most common prepubertal primary testicular tumor is benign teratoma characterized by a heterogeneous mass with areas of solid, cystic, and calcified components (Pohl et al., 2004). Yolk sac tumor is a homogenous well-vascularized mass. An epidermoid cyst has the unique appearance of hyperechoic and hypoechoic rings or “onion rings” with no internal blood flow (Delaney and Karmazyn, 2013) (Fig. 24.13). In the setting of congenital adrenal hyperplasia, bilateral hypoechoic, hyperemic, heterogenous adrenal rests can be seen in children who have improper steroid replacement or poor compliance. A full discussion of scrotal masses and their appearance is beyond the scope of this chapter but can be found in detail elsewhere in this book.

Undescended Testis

Sonography in the evaluation of routine cryptorchidism should not be pursued

(American Urological Association, n.d.). Multiple studies have confirmed its poor sensitivity of detecting and localizing the undescended testicle, and it does not alter the necessary treatment plan (Tasian and Copp, 2011). A reasonable exception would be cryptorchidism in a difficult-to-examine obese child where the presence of an inguinal testis on sonography would simplify the surgical approach. It is the primary imaging modality in the setting of ambiguous genitalia or severe hypospadias with nonpalpable gonads for detection of Müllerian structures, which can guide subsequent workup (Chavhan et al., 2008) (Fig. 24.14)

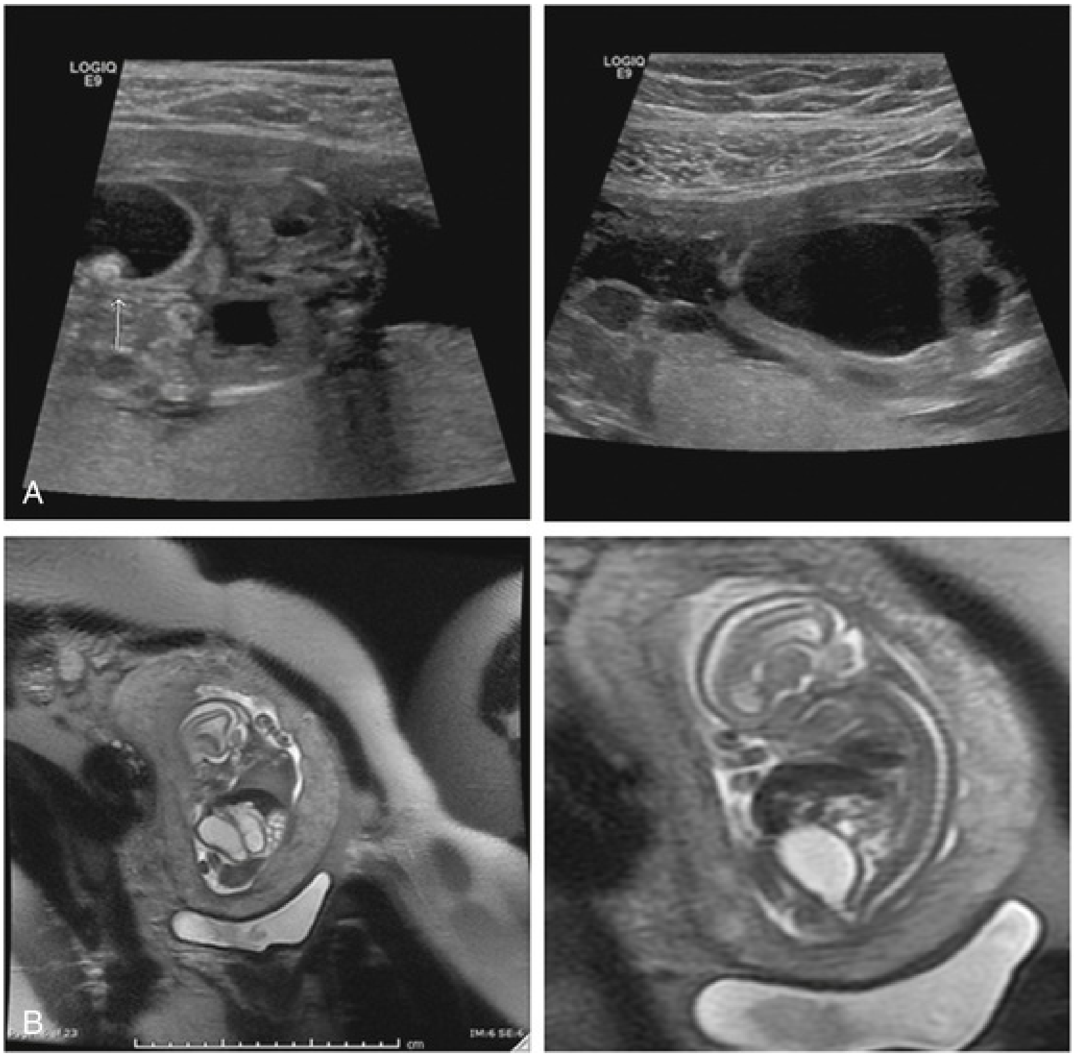

FIG. 24.14 Cryptorchidism in a difficult-to-examine obese child where the presence of an inguinal testis on sonography would simplify the surgical approach. It is the primary imaging modality in the setting of ambiguous genitalia or severe hypospadias with nonpalpable gonads for detection of

müllerian structures that can guide subsequent workup.

Key Points: Undescended Testis

- Sonography for the undescended testis is unreliable and should not be employed, perhaps with the exception of seeking the inguinal undescended testis in an overweight boy.

Differences of Sex Development

Although sonography plays little role in the initial evaluation of the routine undescended testis, it forms the basis for identification of internal genital structures in cases of differences in sex development, presenting as hypospadias with unilateral or bilateral nonpalpable testes, or genital anomalies in females (Guerra-Junior et al., 2018; Lambert et al., 2010).

Magnetic Resonance Imaging

Fundamentals of MRI in the Fetus and Child

MRI is generally used to characterize complex congenital anomalies when sonography is unable to provide sufficient detail. It is not as helpful in the setting of infection, stones, or trauma. Precontrast series may be sufficient to diagnose or confirm other congenital anomalies with great detail such as ectopic ureters, renal duplication anomalies, renal cysts, and calyceal diverticula. Certainly cost, accessibility, and need for sedation in young children limit its overall use.

Protocol

Magnetic resonance urography (MRU) is an excellent approach to providing anatomic and functional information for the urinary tract. Studies are typically performed after an intravenous hydration protocol using normal saline, with a Foley catheter in place. In addition, furosemide can be given either before or during the study. The combination of these two steps improves and hastens urinary tract distention and minimizes artifact during contrast-enhanced imaging. Before contrast administration, a variety of T2-weighted (fluid-sensitive) fast spin-echo (FSE) sequences are obtained, using a combination of rapid-acquisition (single-shot) sequences for quick anatomic assessment, and longer two-dimensional and three-dimensional FSE sequences with better resolution. Three-dimensional sequences can be reconstructed to optimize visualization of the urinary tract. After contrast, T1-weighted gradient-recalled echo images are initially acquired dynamically to provide assessment of renal vasculature, parenchymal enhancement, and excretory function. Dynamic acquisition can be used in functional assessment, most commonly performed via the Patlak method. Subsequently, delayed postcontrast images are obtained to improve delineation of the ureteral course.

MRI is performed in conjunction with a third-level obstetric ultrasound examination after approximately 20 weeks' gestational age.

Given the high sensitivity of MRI, any anatomic details that can be imaged with sonography are more easily appreciated by MRI.

Sedation in the Child

This standard protocol typically takes up to 1 hour to perform; a shortened format has been recently described that can be done in approximately 30 minutes, but larger studies need to be performed to compare efficacy. Given the length of the study, conscious sedation using Propofol, or in some cases general anesthesia, is often required for patients younger than 6 years of age. Imaging techniques to obviate the need for sedation include respiratory-triggered sequences in which scanning is only done when the child holds his or her breath. However, this increases the length of the study. Child life specialists can also help obviate the need for sedation by providing examination preparation and coping techniques.

Kidney/Ureter

Hydronephrosis/Obstruction

In the evaluation of hydronephrosis, MRU is a plausible alternative to the diuretic renogram with far superior anatomic resolution and no radiation exposure (Fig. 24.15). The detailed imaging can provide pinpoint localization of anatomic abnormalities, differential function, and assessment of drainage that can assist in surgical planning. Protocols and formulas have been developed to determine renal function and assess drainage (Jones et al., 2004). Many different protocols have been developed but are similar to those used in MAG3 diuretic renography. The contrast used is gadolinium-based. The child should be well hydrated and furosemide (1 mg/kg; max 20 mg) is given. Timing of the furosemide administration, bladder catheterization, and patient positioning varies by protocol (Darge et al., 2013; Vivier et al., 2010b). Precontrast T2 sequences are first obtained followed by three-dimensional T2 sequences with fat saturation and 1-mm slice thickness. The contrast is then slowly injected and a T1 fat-saturated dynamic scan is continued until contrast has filled the ureters (Darge et al., 2013). This method does require complex postprocessing by a clinician who is specialized in these techniques, which has thus far limited its widespread adoption. It is possible to use free programs such as “chop-fmru” (www.chop-fmru.com) or Image J (National Institutes of Health) to assist in generation of the functional analysis (Khrichenko and Darge, 2010; Vivier et al., 2010a). Its application in children is promising, but studies to confirm its equivalence to diuretic renography and widespread education on interpretation are still needed (Grattan-Smith and Jones, 2006; Perez-Brayfield et al., 2003).

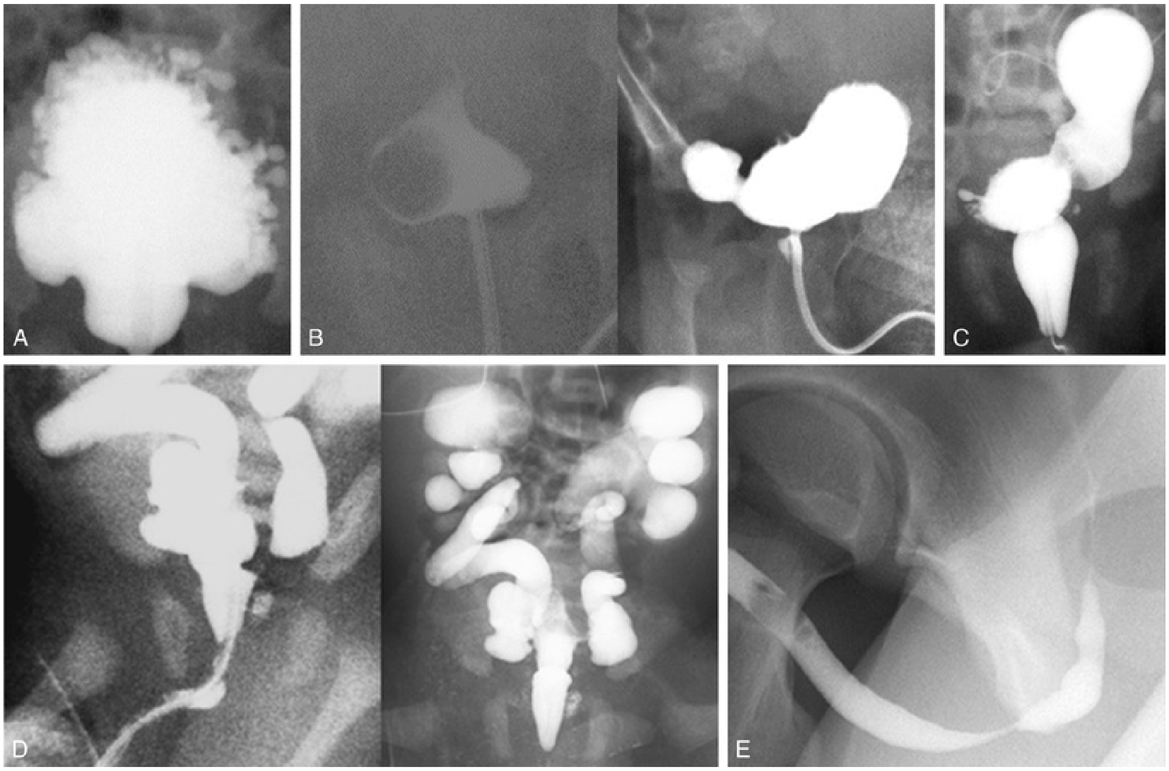

FIG. 24.15 Various findings on voiding cystourethrography scan. (A) A highly trabeculated bladder. (B) A ureterocele within the bladder *(left)* and then everting *(right).* (C) A large bladder diverticulum and elongated posterior urethra in a child with posterior urethral valve. (D) An elongated posterior urethra secondary to a posterior urethral valve and bilateral grade 5 vesicoureteral reflux. (E) A short distal bulbar urethral stricture.

Cysts/Masses/Stones

Much less helpful for the evaluation of stones, MRI is useful for the evaluation of renal complex renal cysts and renal masses. The sensitivity and specificity of MRI compares favorably to CT for detecting capsular penetration of renal masses (Sensitivity 62.9% vs. 68.6%, $P = 0.73$; Specificity 86.5% and 83.8% ($P = 1.0$). MRI was similarly accurate as CT for the detection of lymph node metastasis. However, MRI performs better than CT for the detection of synchronous contralateral lesions (Servaes et al., 2015).

Infection

Although gadolinium-enhanced MRI can image acute inflammatory lesions associated with pyelonephritis, its use is impractical because of the need for long sedation times required to acquire images and rarely is additional information obtained that is relevant to patient care. By comparison to other cross-sectional modalities, such as DMSA single photon emission CT (SPECT) and contrast-enhanced CT, gadolinium-enhanced MRI has similar accuracy for the detection of pyelonephritis (Majd et al., 2001).

Other Congenital Malformations

When confronted with complex anatomy, MRU provides anatomic details that can be helpful (Dickerson et al., 2015).

Bladder/Urethra

Although MRI can be used to evaluate the lower urinary tract, it is rarely more sensitive than a well-performed sonogram. However, MRI is extremely useful at further delineating masses felt to arise from the bladder, particularly rhabdomyosarcoma. Sequences might include a coronal wide–field-of-view short tau inversion-recovery sequence, diffusion-weighted imaging (b = 0, 100, or 600 sec/mm^2), nonenhanced and gadolinium-enhanced imaging of the pelvis, a three-dimensional volumetric T1-weighted sequence, and axial and sagittal T2-weighted fat-saturated sequences (pedsMRI app). Because urine masks hyperintense lesions on T2-weighted images, it is useful to employ nonenhanced T1-weighted imaging and to employ fast sequences to obtain images before gadolinium accumulates significantly within the tissues (Hoffer, 2005). On MRI, rhabdomyosarcoma demonstrates uniformly low signal intensity on T1-weighted images and heterogeneous high signal intensity on T2-weighted and contrast-enhanced T1-weighted fat-saturated images (Nigro and MacLennan, 2005). These differences in signal intensity have been ascribed to areas of tissue necrosis. Lastly, although MRI has proved useful in tumor staging, there are no features particular to the tumor itself that predict tumor subtype.

Scrotum/Testes/Internal Genitalia

Acute Scrotum

MRI plays no role in the evaluation of the acute scrotum.

Cysts/Masses

Although MRI plays no role in the evaluation of cysts and masses of the scrotum and testes, one might consider its use for tumor staging in patients with testicular cancer. Historically, CT of the abdomen with intravenous contrast has been used for tumor staging of the chest and abdomen, but the information obtained by MR sequences is predictably similar.

Undescended Testis

Sensitivity and specificity of MRI in comparison to sonography for identification of internal structures including gonadal detection is marginally better at best (Biswas et al., 2004; Gambino et al., 1992; Mansour et al., 2012).

Differences of Sex Development

In the setting of differences of sexual development, sonography and urogenitography are typically the only studies needed for both diagnosis and surgical planning. However, a few very complex cases have sometimes benefited from the additional anatomic information obtained on MRI. Overall, the expense and sedation requirement likely does not justify the routine use of MRI to understand this pelvic anatomy.

Conventional Radiography

Plain Abdominal Radiography

Plain abdominal radiography or KUB testing has been used not only for detection of radiopaque stones, but also for evaluation of constipation in children with voiding dysfunction. Unfortunately, there is little data to support its accuracy in detecting or evaluating treatment for constipation (Berger et al., 2012; Reuchlin-Vroklage et al., 2005). It can, however, provide impressive visual evidence for parents who are dubious of the diagnosis of constipation and therefore its treatment despite the child's clinical signs and symptoms.

Intravenous Pyelography

Intravenous pyelography has fallen out of favor with the advent of the previously mentioned modalities offering high-resolution anatomic studies and predictably reproducible functional studies. The IVP consists of multiple sequential radiographs throughout the excretion and drainage of contrast material and in different focal planes in attempts to obtain anatomic and functional information. Accurate localization of obstructive lesions and radiopaque stones can be seen on a well-performed study. Drainage time can also be assessed, although not as precisely as in diuretic renography.

Retrograde Pyelography

Retrograde pyelography involves injection of contrast into the ureteral orifice requiring anesthesia in a child. This is best used for intraoperative localization of an obstructive lesion identified preoperatively using other studies. However, free retrograde flow cannot be assumed to equate free, unobstructed antegrade flow and vice versa, especially after a prior surgical repair. For example, small postsurgical tissue flaps can cause obstructed antegrade flow but give an unobstructed appearance on retrograde pyelography.

Voiding Cystourethrography/Micturating Cystourethrogram

Fundamentals of Voiding Cystourethrography

Also known as VCUG and micturating cystourethrogram (MCUG), respectively, this test assesses the function of the lower urinary tract. Historically performed without sedation, clinicians have long recognized how invasive this study is on children, and protocols have been developed for mitigating pain and anxiety. When obtained to evaluate urinary tract infection, it is regarded as routine to defer VCUG at least until after the patient has received several days of antibiotics and is clinically improving.

After catheterization of the bladder, a brief fluoroscopic image ensures proper placement of the tip of the catheter in the bladder and that not too much catheter has been advanced. Failure to visualize the catheter in the midline suggests malposition, which might occur, for example, because of an abnormality of the utricle or posterior urethra in the male or into an ectopic ureter in the female. Additionally, too much catheter in the bladder can result in knotting of the catheter itself.

Kidney/Ureter

Obstruction

VCUG has been obtained routinely as part of the evaluation of children with hydronephrosis; however, the need to do so has been challenged (Kim et al., 2001; Yerkes et al., 1999). Instead, most algorithms reserve VCUG when hydronephrosis is seen along with dilated ureter(s).

Cysts/Masses

There is no renal cystic disease or mass that is specifically evaluated by VCUG.

Infection

VCUG has been delayed between 4 and 6 weeks after UTI, when it is indicated, on the premise that early MCUG/VCUG might demonstrate mild transient VUR created by inflammatory changes at the trigone. However, because it is rare for clinically significant VUR present during infection to disappear after treatment and because the identification of even transient VUR during UTI might be clinically meaningful, a prolonged waiting period is not necessary (Craig et al., 1997; Gross and Lebowitz, 1981). If VUR is detected on a MCUG performed early in the course of febrile UTI, it should be considered that ureteral dilation caused by endotoxin overestimates the degree of VUR (Hellström et al., 1987; Roberts, 1975).

Other Congenital Malformations

There are no congenital malformations of the kidney and ureter, other than ureterovesical junction anomalies, that benefit from VCUG evaluation.

Trauma

There is no renal or ureteral trauma that is specifically evaluated by VCUG.

Bladder/Urethra

Obstruction

VCUG is an excellent high-resolution anatomic study that is used to detect abnormalities such as those of the bladder wall (e.g., trabeculation, ureterocele, diverticula, bladder neck hypertrophy, tumors), those of the urethra (posterior urethral valve (Fig. 24.16), urethral stricture, diverticulum), bladder stones, bladder rupture, and foreign bodies. VCUG can be used to assess bladder emptying. The initial scout film can also identify many spinal abnormalities.

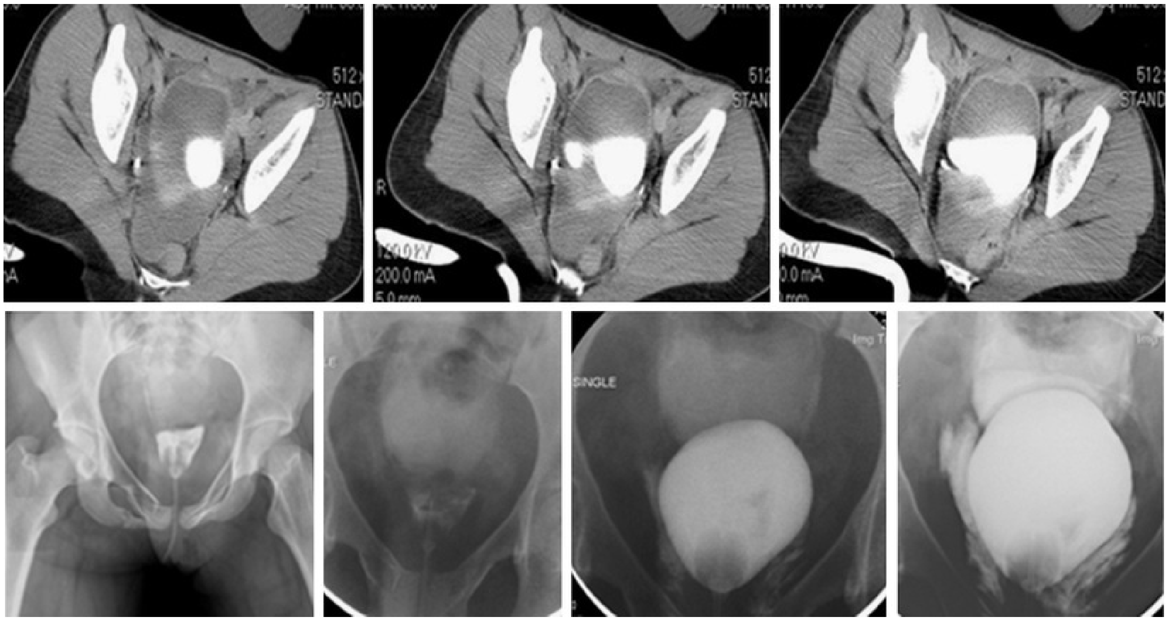

FIG. 24.16 A 15-year-old female patient with a pelvic fracture undergoes a screening computed tomography scan suggesting a bladder injury, which is confirmed by contrast cystography. Note the extreme elevation of the bladder neck (pie-in-the-sky) on the cystogram and clear demonstration of contrast collecting in the retroperitoneal space.

Cysts/Masses

Among the dilations and masses identified on VCUG, one finds urachal diverticula, bladder diverticula, dilated utricles, and fibroepithelial polyps.

Infection

VCUG likely provides little added information in the child with a single or few episodes of nonfebrile UTI (cystitis or urethritis); however, with increasing severity or frequency of recurrence, some would advocate for obtaining a VCUG to exclude anatomic risk factors for UTI. In circumcised males, particularly, the risk for UTI is exceedingly low such that any UTI in those patients might deserve evaluation.

Other Congenital Malformations

Positional instillation of contrast cystography is used sparingly with good effect for diagnosis of occult VUR in select children with a negative VCUG but persistent febrile UTIs despite treatment of all other potential etiologies (Hagerty et al., 2008b; Rubenstein et al., 2003). It is important, however, to perform the test properly with passive instillation of contrast at a height of 1 meter above the bladder as originally described to avoid creation of purely iatrogenic VUR (Hagerty et al., 2008a).

Trauma

Contrast imaging of the bladder and urethra is certainly indicated in circumstances of pelvic trauma, especially when blood is seen at the urethral meatus and/or the patient complains of difficulty voiding. Urethral injuries would be the most likely finding in these cases, and prompt intervention is mandatory (Fig. 24.17).

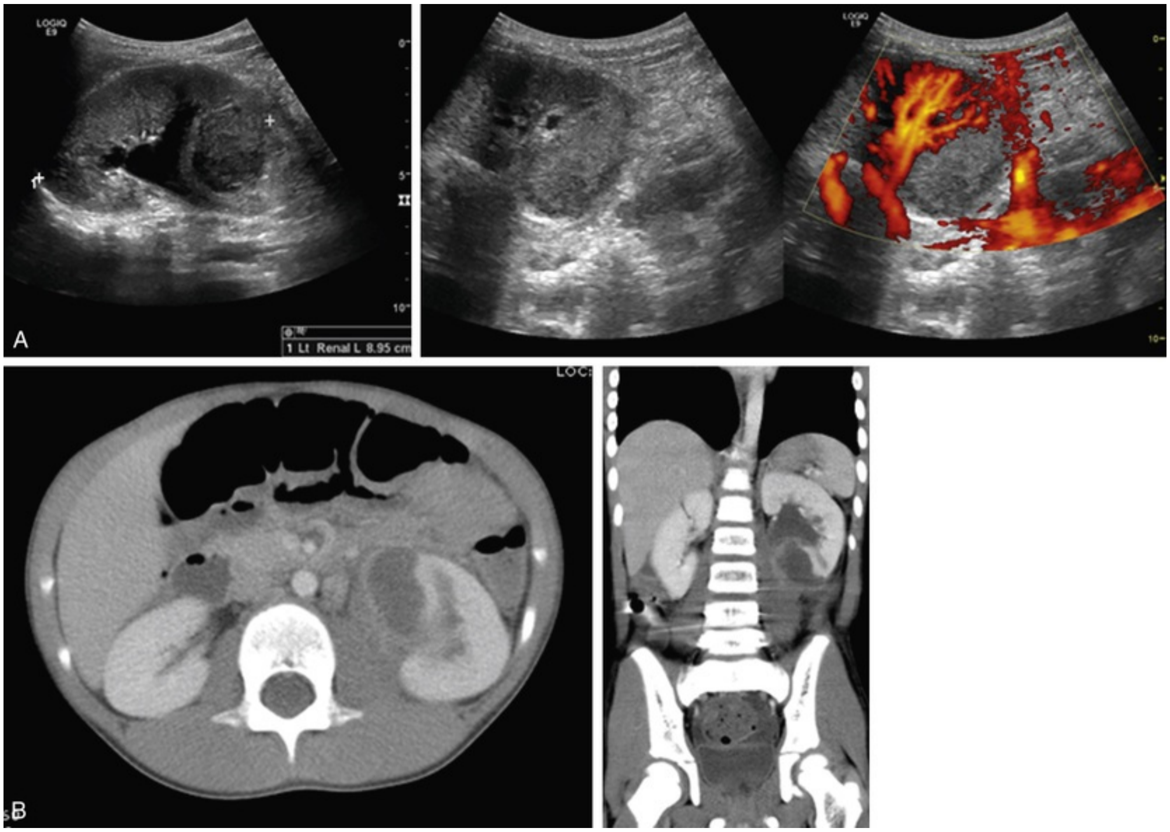

FIG. 24.17 A 6-year-old male patient presenting with abdominal pain, elevated erythrocyte sedimentation rate and C-reactive protein, and inability to stand erect. (A) A sonogram of the kidneys with Doppler views demonstrates a heterogeneous collection in the lower pole of the left kidney. (B) This region is confirmed on the computed tomography scan as a renal abscess.

Scrotum/Testes/Internal Genitalia

VCUG is not useful in the evaluation of genital anomalies with the exception of assessing urethral, bladder, and internal genital anatomy in cases of cloaca and urogenital sinus or differences in sex development.

Differences of Sex Development

Urogenitography can provide essential information for surgical planning and classification of patients with disorders of sexual differentiation. Typically a catheter is placed within the single perineal opening and contrast is injected under fluoroscopy to identify the confluence of urethral and vaginal structures as well as their orientation. Alternatively, a Foley catheter can be used with the balloon inflated and pressed up to the perineum with the tip in the perineal opening for retrograde filling (Chavhan et al., 2008). Results of the urogenitogram can be classified based on Shopfner's classification scheme (Shopfner, 1964) (Fig. 24.18).

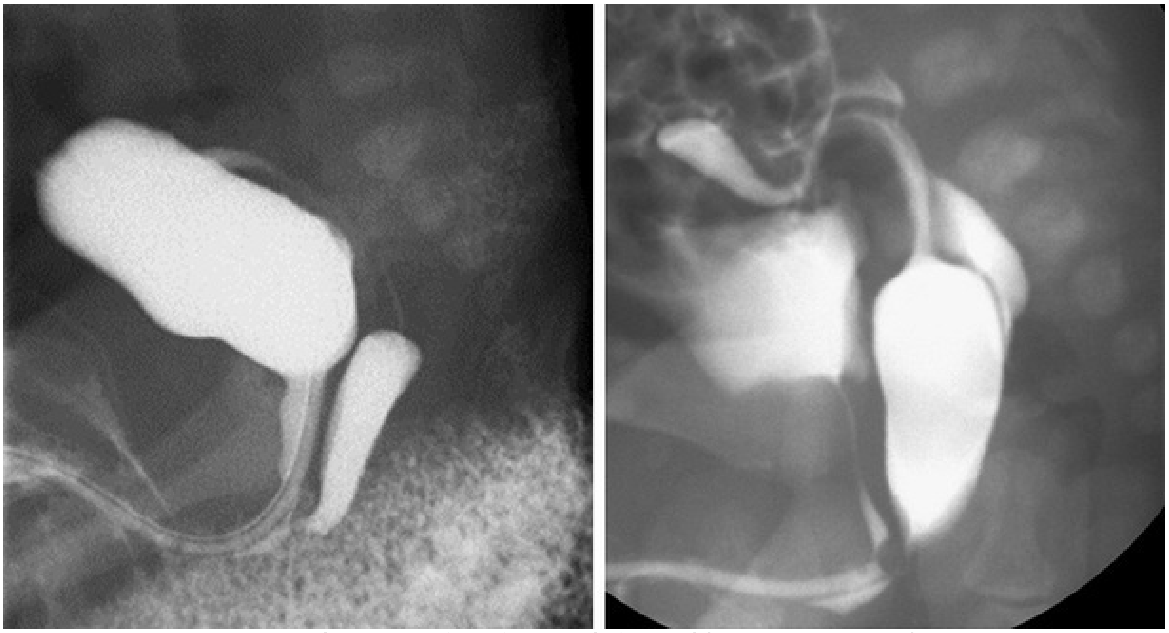

FIG. 24.18 Genitogram of an female infant with 46,XX ovotesticular disorder of sex development showing a low confluence of the urethra and vagina and reflux into the right fallopian tube. This is consistent with a Shopfner type III classification.

Computed Tomography

Fundamentals of CT Imaging in Children

The role of CT in children is less based on its diagnostic capabilities as it is on its availability and quick acquisition time. This advantage is best realized in cases of blunt abdominal trauma and polytrauma. However, with advances in sonography and MR, its need in pediatrics at the cost of potentially harmful radiation exposure is dwindling.

Kidney/Ureter

Obstruction

CT has little role in the evaluation of pediatric hydronephrosis as it offers little advantage over sonography with unwanted ionizing radiation. Like sonography, it is a detailed anatomic study but with the ability to imply function in noncalcareous hydronephrosis with the addition of intravenous contrast and delayed images. Although a delayed nephrogram and ureteral drainage compared with the contralateral side signals obstruction, this is difficult to quantitate. It can give detailed anatomic information in the setting of renal and ureteral anomalies in the more complex patient (e.g., those with ectopic kidney, ectopic ureter, megaureter, duplication anomalies, renovascular anomalies), which may be helpful in surgical planning when sonography or MRI are inconclusive or unavailable.

Cysts/Masses

The use of contrast-enhanced CT scans for evaluation of pediatric renal tumors is commonplace. A variety of solid renal masses commonly seen in children include congenital mesoblastic nephroma, neuroblastoma, Wilms Tumor, clear cell sarcoma, rhabdoid tumors, solitary multilocular cyst, metanephric adenoma, renal cell carcinoma, and angiomyolipoma. A full description of individual presentations of each renal tumor, of their natural history and management is found in Chapter 53.

Infection

CT has a limited role in the setting of childhood UTI and is best reserved for situations in which nonionizing modalities are inconclusive. Both MRI and CT imaging can be helpful in assessing infections related to renal abscess, extraurinary fistualization, and postoperative complications and secondary to urinary obstruction (Fig. 24.19).

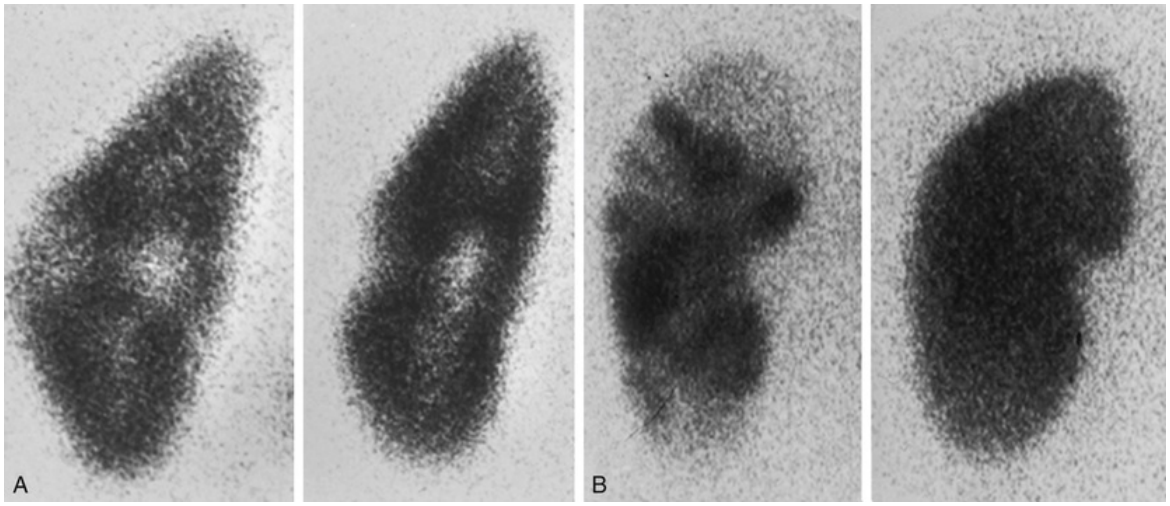

FIG. 24.19 Dimercaptosuccinic acid renal scans (A and B) demonstrating areas of photopenia with preservation of the renal contour consistent with acute pyelonephritis. The patient on the left (A) demonstrates formation of a renal scar, which can be differentiated from the acute lesion because of loss of the renal contour. The patient on the right (B) demonstrates complete resolution of all areas of APN after 6 months.

Calculus Disease

The most obvious advantage of CT is in the detection of urolithiasis. It is certainly better than sonography at detecting and quantifying stone burden, however, it has been shown that this increased accuracy is seldom clinically impactful (Passerotti et al., 2009). Care should be taken to follow the ALARA principle when choosing to use CT in all patients, but especially children with stone disease who will likely have a lifetime of frequent imaging episodes.

Trauma

CT with and without intravenous contrast is routinely used in the evaluation of pediatric abdominal trauma. When performed, it is imperative to obtain adequately timed images to thoroughly visualize the urinary tract. Frequently, in the rush to evaluate trauma patients, postintravenous enhanced images are obtained during the “arterial phase” when only the renal cortex is enhanced. Although this provides information regarding renal cortical contusion or laceration, injuries to the renal collecting system or ureter may not be seen.

Bladder/Urethra

CT plays little role in the evaluation of obstruction, infection, or congenital malformations of the lower genitourinary tract. Although it may be employed for the evaluation of bladder masses, MR may be preferred over CT because of its better resolution of soft tissues.

Trauma

CT of the lower tract and genitalia is typically reserved for detection of bladder or pelvic trauma. CT cystography can be performed either by antegrade/delayed filling or retrograde filling with a catheter to detect bladder/augment rupture. Although this could be performed with a conventional cystogram, CT can provide better anatomic resolution and immediate classification of such rupture as intraperitoneal or extraperitoneal, which would affect management options.

Scrotum/Testes/Internal Genitalia

CT has no role in the evaluation of the acute scrotum, cysts/masses of the external genitalia, or undescended testis, or for differences of sex development. CT scanning is part of the staging evaluation for testicular and paratesticular masses to assess for metastatic disease.

DMSA Renal Cortical Scintigraphy

Renal cortical scintigraphy using DMSA relies on uptake by proximal tubular cells, a process that is dependent on renal blood flow (Majd and Rushton, 1992). Focal renal blood flow is decreased in sites of acute pyelonephritis, which corresponds to areas of relative photon deficiency seen on DMSA scans (Rushton and Majd, 1992). Although AP lesions appear as areas of decreased peripheral uptake with preservation of the reniform contour, renal scars can be differentiated based on observation of volume loss that interrupts the normal reniform outline, thus resulting in concavity. These lesions can be focal, multifocal, or diffuse. Although it is possible for an experienced observer to distinguish between acute and chronic lesions, differentiation is frequently difficult in those kidneys with AP superimposed on preexisting renal scars. Using histopathologic criteria in a piglet autopsy study of induced AP, the sensitivity and specificity of DMSA for AP was 87% and 100%, respectively (Rushton et al., 1988). A similar experiment demonstrated slightly higher sensitivity with lower specificity but equivalent diagnostic accuracy when using single-photon emission computed tomography (SPECT) detection compared with planar (pinhole) detection (Majd et al., 1996).

The timing of DMSA scintigraphy is determined by whether one is seeking to document the acute inflammatory changes of pyelonephritis, or instead, irreversible renal cortical scarring. Because inflammation is a transient process, acute changes are reliably seen when the DMSA scan is obtained within days of the acute episode that gradually resolves over the next 5 months such that by 6 months any lesion demonstrated on scintigraphy is likely a fixed scar (Ghasemi et al., 2013; Stokland et al., 1996a, 1996b). Acute DMSA scan lesions persist in 36% to 52% of kidneys (Rushton and Majd, 1992) (see Fig. 24.19).

Diuretic Renal Scintigraphy

The gold standard for differentiation of obstructive and nonobstructive hydronephrosis/hydroureter is diuretic renography. This can be accomplished with either ^{99m}Tc-diethylenetriamine pentaacetic acid (DTPA) or more commonly, ^{99m}Tc-mercaptoacetyltriglycine. A strict protocol should be followed to ensure accurate and reproducible results (Conway and Maizels, 1992; Majd, 1989; Shulkin et al., 2008). There are four key elements to a successful diuretic renogram: (1) hydration, (2) selection of the appropriate region of interest (ROI) and background subtraction, (3) bladder drainage, and (4) timing of diuretic administration. An intravenous line is placed for hydration before the study in addition to encouragement of oral hydration before arrival because the dehydrated patient responds poorly to diuresis (Fig. 24.20). A catheter is helpful in eliminating any concerns of bladder filling affecting upper tract drainage, difficult interpretation secondary to VUR, or increased gonadal radiation exposure caused by radioactive urine. The ROI must be tightly drawn around either the renal cortex (for determination of differential renal function) or around the dilated collecting system (for measurement of drainage). The region of background subtraction should be similarly tightly drawn, being careful to include regions adjacent to the kidney and within the confines of the body. Inclusion of the wrong portion of the urinary tract in an ROI can result in spurious measurements (Fig. 24.21). Intravenous furosemide (1 mg/kg) is given when the dilated collecting system is determined to be maximally filled and not before. Differential renal function, washout curves, and washout half-times can then be computer-generated; however, additional features might be helpful in predicting natural history (Shalaby-Rana et al., 1997). For instance, we have observed that patients demonstrating a biphasic drainage curve, characterized by initial prompt drainage that ceases, or patients with poor gravity-assisted drainage, are more likely to progress to high-grade obstruction when followed over time (Fig. 24.22). Thus, management decisions should be made based on patient age, renal function, diuresis half-life, curve shape, and upright clearance. The clinician should be sure to review the actual drainage images, regions of interest used, and curves as any variation in technique can lead to misleading results. Unlike in adults, in children there are no established washout half-lives that define an obstructed or unobstructed state, and often repeat scans are required during longitudinal follow-up (Fig. 24.23). Diuresis renography can be helpful in the evaluation of intermittent obstruction. Reduction in renal blood flow as a result of increased intrapelvic pressure is suggested by the finding of cortical retention of tracer (akin to an obstructed nephrogram on an intravenous pyelogram). Cortical retention of tracer is seen up to 48 hours after the acute event, even when the hallmark features of Dietls crisis has resolved (nausea or vomiting and flank or abdominal pain) (Figs. 24.24 and 24.25). By comparison to renal sonography, diuresis renography provides a more reproducible and quantifiable evaluation of the urinary tract when properly performed (Fig. 24.26).

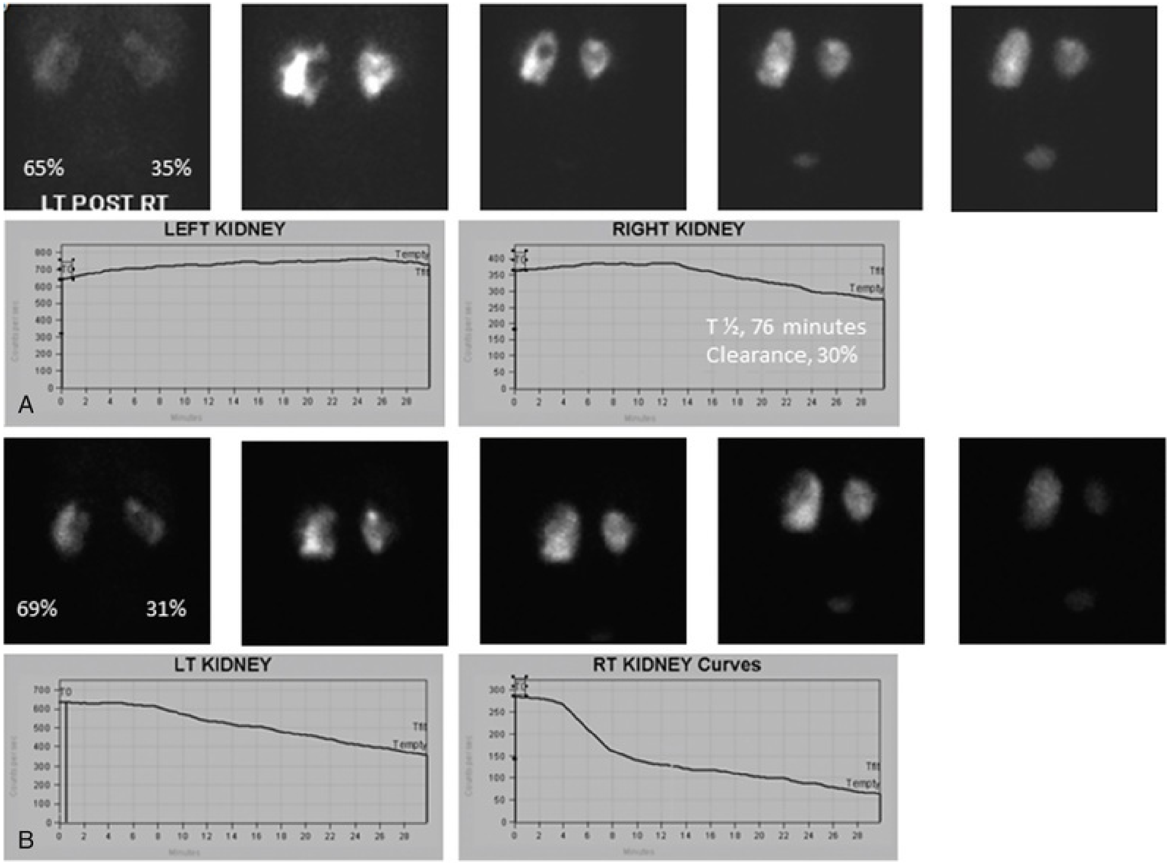

FIG. 24.20 The importance of controlling for patient hydration is apparent in this diuresis renogram being used to evaluate hydronephrosis in a young child after bilateral pyeloplasties. (A) The patient had been nothing by mouth (NPO) overnight for planned sedation during the diuresis renogram. Despite fluid resuscitation with 375 mL, only 30 mL of urine were drained through the urethral catheter. Cortical transit through both kidneys was observed to be poor, as well as drainage from both collecting systems. (B) The diuresis renogram was repeated 2 months later without NPO restrictions and with more aggressive hydration with 565 mL, which

resulted in diuresis of 425 mL of urine through the urethral catheter. Diuresis-induced drainage half-lives were improved for both kidneys, on the left side.

FIG. 24.21 The importance of selecting the correct region of interest *(ROI)* is apparent in this diuresis renogram being used to evaluate hydronephrosis and hydroureter in an infant. Furosemide is administered 30 minutes after administration of radiotracer with a diuresis half-life being calculated from the time when the tracer rather than when the furosemide is administered. When calculated in this fashion, the half-life ($T_{½}$) includes the time for tracer to pass through the cortex and to be secreted into and accumulate in the dilated collecting system. Instead, calculation of half-life should be made based on the time required for 50% of the tracer to drain from the dilated collecting system, annotated as TMax in this example. A to C, The effect of differing ROIs on the drainage curves for the left kidney confirms that obstruction does not exist at the level of the ureteropelvic junction but instead at the level of the ureterovesical junction.

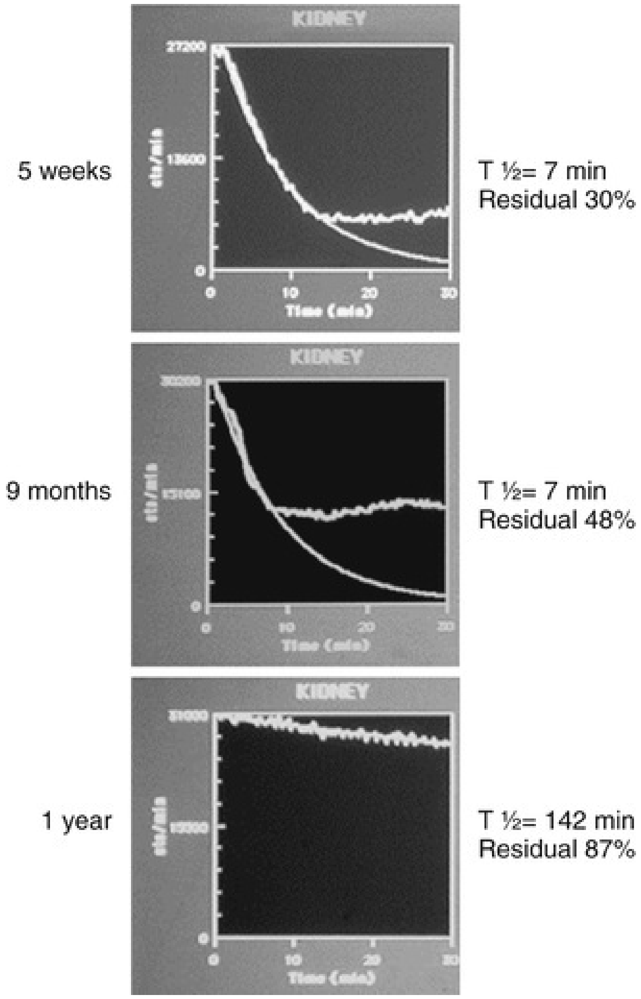

FIG. 24.22 A single diuresis renogram may not be sufficient to exclude obstruction. In this example, three consecutive MAG3 diuresis renograms on the same patient demonstrate progressively poor drainage (prolongation of the $T_{1/2}$ and retention of tracer).

FIG. 24.23 Demonstration of the utility of gravity-assisted drainage (A) Initial MAG3 diuretic renogram at 42 days of age demonstrates asymmetric renal function with gradual accumulation of tracer within dilated collecting systems. (B) Diuresis results in indeterminate drainage from *both* collecting systems (right $T_{1/2}$ 20 minutes, left $T_{1/2}$ 11 minutes). After 30 minutes of

diuresis, equal amounts of tracer has cleared from both collecting systems: 65% *(right)* and 64% *(left)*. (C) After 15 minutes of upright positioning providing gravity-assisted drainage, there is additional clearance from both renal pelves, but more on the left than on the right. Follow-up MAG3 diuretic renogram at 8 months of age demonstrates worsening of renal function on the right side with delayed excretion of tracer into the right renal pelvis, and early spontaneous drainage of tracer from the left renal pelvis before administration of diuretic. (D) Diuresis results in accumulation of tracer in the right renal pelvis and further drainage from the left renal pelvis. (E) Diuresis curves demonstrate prompt drainage from the *left* renal pelvis; on the *right* drainage is negligible. (F) After 15 minutes of upright positioning, there is very little additional clearance from the right renal pelvis.

FIG. 24.24 (A) MAG3 diuresis renograms performed on a 3-month-old infant with prenatally detected hydronephrosis. The dilated right collecting system appears to drain well initially but demonstrates a prolonged half-life on repeat renography at 2 years of age (B). This child was managed with pyeloplasty based on these findings.

FIG. 24.25 Ultrasound scan shows mild right hydronephrosis in a 7-year-old male patient with right upper quadrant pain. (A) Diuresis renogram shows nonobstructive drainage. The patient presented a second time with pain. This time, the sonogram showed increased dilation of the right collecting system. (B) Diuresis renogram demonstrates worse drainage, and the patient reported pain after furosemide (Lasix) administration. (C) After pyeloplasty, renography shows prompt spontaneous drainage; furosemide was not administered. $T_{1/2}$, half-life.

FIG. 24.26 (A) Initial diuresis renogram shows mild right hydronephrosis. After administration of furosemide (Lasix), there was rapid clearance of the tracer from the pelvicalyceal system with the washout half-life ($T_{1/2}$) of 2 minutes. A few minutes later, the patient developed right flank pain, and there was gradual accumulation of the tracer in the right kidney (rising second part of the curve) (A). (B) Postoperative differential renal function remained stable, and drainage improved significantly.

Radionuclide Cystography

Direct radionuclide cystography can be accurately used for detection of VUR with greater sensitivity and lower radiation exposure than standard VCUG (Brown et al., 2000; Sukan et al., 2003; Unver et al., 2006). However, it lacks the anatomic resolution of the collecting system and urethra, still requires urethral catheterization, and is still a nonphysiologic measurement. Exact grading comparisons to VCUG can be difficult but are certainly possible (Fretzayas et al., 1984; Polito et al., 2000; Unver et al., 2006; Zhang et al., 1987). Indirect radionuclide cystography can be performed without catheterization after radionuclide renography and provides a noninvasive, physiologic test, but it is not as sensitive as direct methods so is not routinely used for the purpose of VUR detection (Bower et al., 1985) (Figs. 24.27 and 24.28).

FIG. 24.27 Sonography may not be sufficient to identify obstruction. (A) Renal sonogram demonstrating *moderate* (SFU grade 3) hydronephrosis (mostly intrarenal dilation) without hydroureter. The renal cortex is well preserved as cortico-medullary differentiation is present and there is no sonographic evidence of renal cortical cysts. The left kidney is normal. (B) ^{99m}Tc-MAG3 Lasix renal scan showing high-grade ureteropelvic junction obstruction with reduced renal function from the right kidney (31%). The diuresis curve demonstrates no drainage, and instead, reflects continuous accumulation of tracer in the right collecting system.

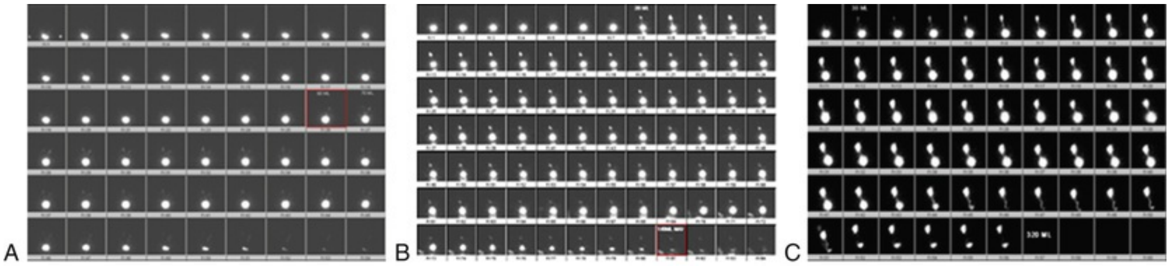

FIG. 24.28 Radionuclide cystography examples of mild (A), moderate (B), and severe (C) vesicoureteral reflux.

Radionuclide Testicular Scanning

Testicular scintigraphy has been around since the 1970s and is typically promoted to distinguish between testicular torsion and inflammatory conditions of the testicle (i.e., epididymitis, orchitis, testicular appendage torsion) (Holder et al., 1981). The test is performed by intravenous injection of ^{99m}Tc-pertechnetate followed by dynamic and static gamma images of the pelvis. Similar to renal scintigraphy, photon-deficient areas represent poor blood flow as in torsion, and photon-hyperdense areas can represent inflammation as in epididymitis. In experienced centers, this technique can be very sensitive and specific (up to 100%) and potentially perform better than sonography in the setting of the acute scrotum (Flores et al., 1996; Mendel et al., 1985; Wu et al., 2002). However, its lack of availability, invasiveness, and radiation exposure limit its widespread adoption over sonography. Perhaps the most appropriate use is in cases that are equivocal by examination and sonography, but only if potentially testicle-saving surgery is not unreasonably delayed (Kodali et al., 2013).

Infection and Inflammation of the Pediatric Genitourinary Tract

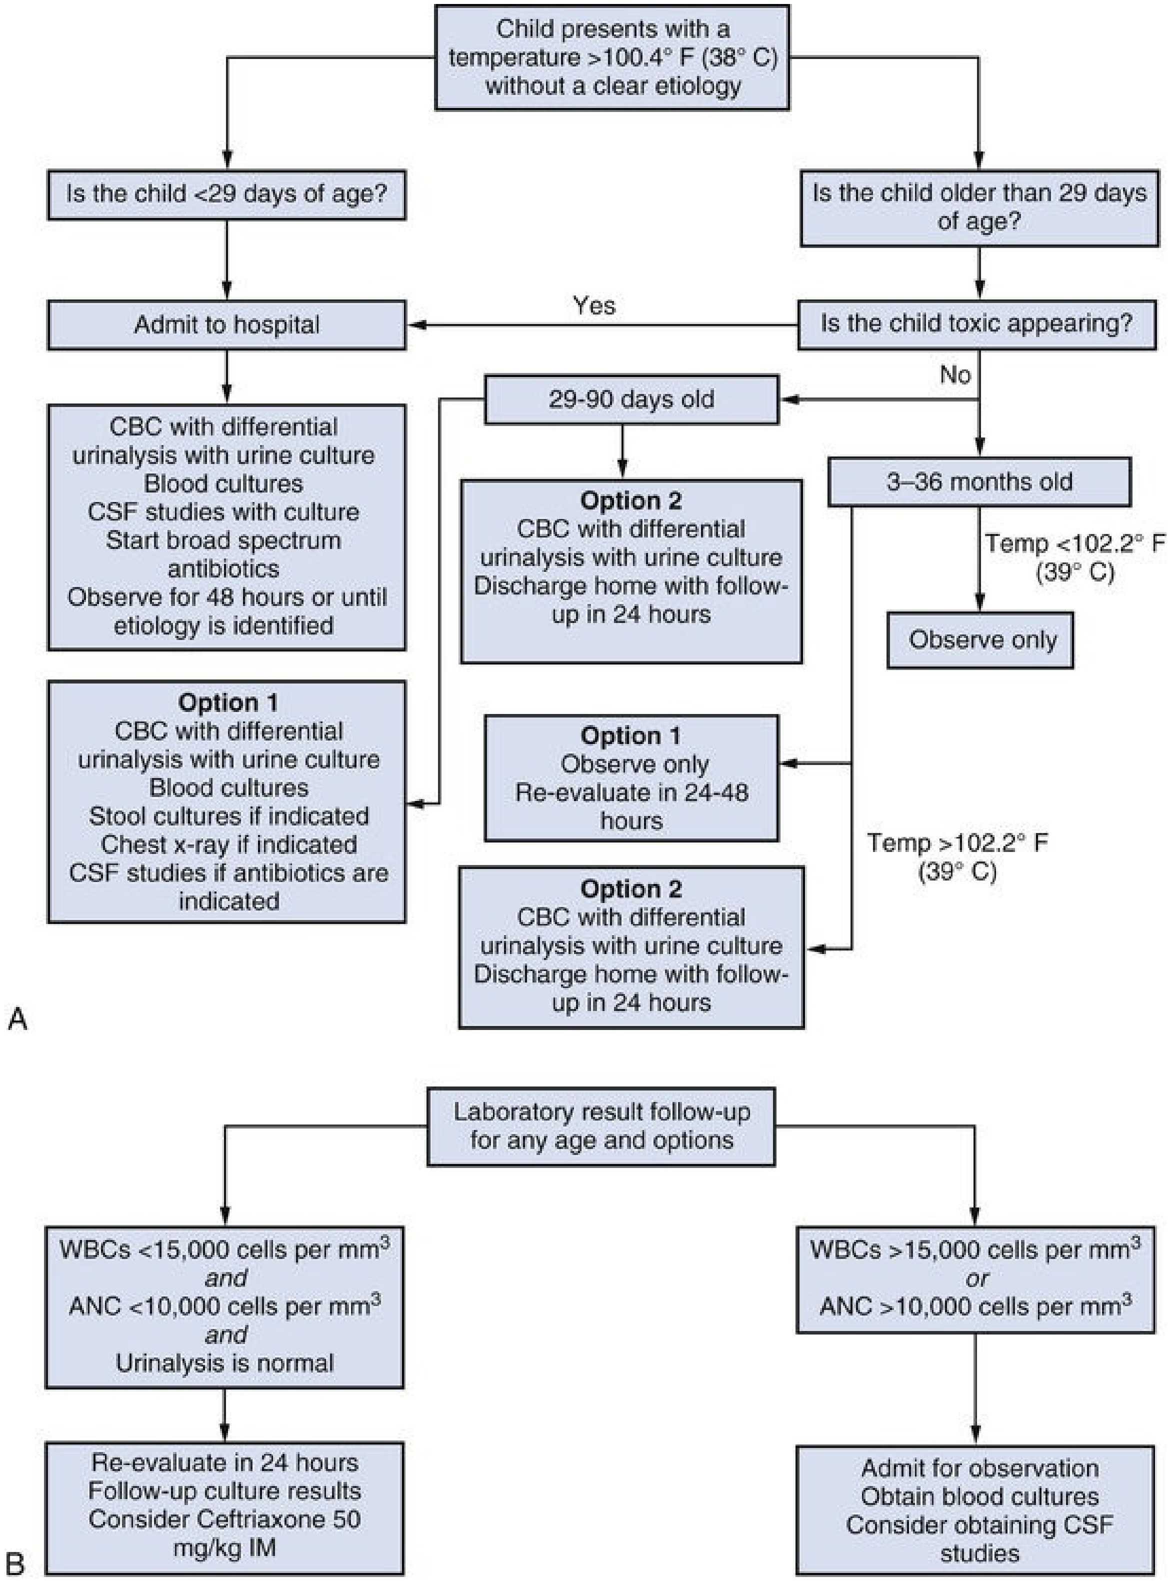
Christopher S. Cooper MD, FAAP, FACS, Douglas W. Storm MD, FAAP

Pediatric urinary tract infections (UTIs) constitute a significant burden to the American public: 2.4% to 2.8% of all American children are affected annually by a UTI, and UTIs account for 1.1 million medical visits per year (Freedman, 2005). Although UTIs are epidemic in children, not all UTIs are the same. Some children have a single, sentinel UTI, whereas others suffer recurrent infections in infancy and into childhood and beyond. Some UTIs are associated with fever, and others only cause lower urinary tract symptoms or malodorous urine. Some UTIs lead to renal scarring, hypertension, and/or end-stage renal disease, whereas others involve no long-term sequelae. Unfortunately, at this time, there is no definitive way to predict whether children will ever develop a UTI, to determine if they will suffer further UTIs, or to determine if they will be affected by long-term medical issues related to their infections. This chapter describes the pathogenesis, evaluation, and management of pediatric UTIs to facilitate the care provider's individualized management decisions for each child.

Evaluation and Management of a Child With a Fever

Infants and young children frequently visit health care providers with a history of fever of undetermined cause. Although an extensive discussion of the workup and management of febrile infants is beyond the scope of this chapter, it is important for all pediatric care providers to have a basic knowledge of the care and evaluation of these patients. For children, a clinically significant fever is generally defined as a rectal temperature of 100.4°F (38°C) or higher (Sur and Bukont, 2007). In a previously healthy child 3 to 36 months of age, a temperature of 39°C or higher warrants further evaluation (American College of Emergency Physicians Clinical Policies Committee, 2003; Baraff, 2000; Baraff et al., 1993). In the majority of these children, the source of their fever is a viral illness; however, 7% to 13% of these children, with no clear fever source, have occult bacteremia and serious bacterial infections (Baraff, 2000; Dagan et al., 1988; Kadish et al., 2000). Serious bacterial infections in these patients include bacteremia, bacterial gastroenteritis, cellulitis, meningitis, osteomyelitis, pneumonia, septic arthritis, and UTIs. These infections are more common in children younger than 90 days and especially in children younger than 29 days. In children younger than 90 days, 7.2% experience a serious bacterial infection, whereas 8.7% to 28% of children younger than 29 days have such a serious infection (Baker and Bell, 1999; Baraff et al., 1993; Ishimine, 2007).

The goal of evaluating the febrile child is to ensure that serious infections are not missed and that proper treatment is initiated quickly. A summary of the evaluation and treatment of a child with a rectal temperature higher than 38°C is provided in Fig. 25.1. In such an evaluation, the ability to detect a child appearing “toxic” is important because these patients show a higher rate of serious infections. Signs and symptoms of toxicity include cyanosis, decreased activity, hyper- and hypoventilation, inability to interact with parents, irritability, lethargy, poor tone, poor perfusion, tachycardia, and poor eye contact (Sur and Bukont, 2007). It is important to keep in mind that although toxic appearance, age younger than 30 days, and rectal temperature of 39.4°C or greater are highly predictive of bacteremia, not one of these features guarantees the identification of a child with a serious bacterial infection, and absence of these features also does not rule out a serious infection (Pantell et al., 2004). In fact, one study demonstrated that a “toxic”-appearing child was 92% likely to have a serious illness when compared with ill or well-appearing children (26% and 3%, respectively) (McCarthy et al., 1982; Teach and Fleisher, 1995).



Child presents with a temperature >100.4° F (38° C) without a clear etiology
Is the child <29 days of age?
Is the child older than 29 days of age?
Admit to hospital
Yes
Is the child toxic appearing?
No
CBC with differential
urinalysis with urine culture
Blood cultures
CSF studies with culture
Start broad spectrum antibiotics
Observe for 48 hours or until etiology is identified
29-90 days old
Option 2
CBC with differential
urinalysis with urine culture
Discharge home with follow-up in 24 hours
3–36 months old
Temp <102.2° F (39° C)
Observe only
Option 1
CBC with differential
urinalysis with urine culture
Blood cultures
Stool cultures if indicated
Chest x-ray if indicated
CSF studies if antibiotics are indicated
Option 1
Observe only
Re-evaluate in 24-48 hours
Temp >102.2° F (39° C)
Option 2
CBC with differential
urinalysis with urine culture
Discharge home with follow-up in 24 hours
A
Laboratory result follow-up for any age and options
WBCs <15,000 cells per mm3
and
ANC <10,000 cells per mm3
and
Urinalysis is normal
WBCs >15,000 cells per mm3
or
ANC >10,000 cells per mm3
Re-evaluate in 24 hours
Follow-up culture results
Consider Ceftriaxone 50 mg/kg IM
Admit for observation
Obtain blood cultures
Consider obtaining CSF studies
B

FIG. 25.1 (A) Algorithm for the treatment of a child from birth to age 36 months with a fever higher than 100.4°F (38°C) with no cause for the fever. (B) Continued considerations for the treatment of a child aged 0 to 36 months with a fever higher than 100.4°F (38°C) with no cause for the fever.

ANC, Absolute neutrophil count; *CBC,* complete blood count; *CSF,* cerebrospinal fluid; *IM,* intramuscular; *WBCs,* white blood cells.

As is discussed in more detail later, the diagnosis of a UTI in children may be difficult because the symptoms can be nonspecific. In children from birth to age 24 months, the presence of a fever higher than 40°C, history of a previous UTI, suprapubic tenderness, and uncircumcised penis are the most useful signs and symptoms in predicting a UTI in a febrile child (Shaikh et al., 2007). Other factors such as vomiting, diarrhea, poor feeding, and irritability are not sensitive nor specific in screening for the presence of a UTI (Shaikh et al., 2007). In children older than 24 months, who are more verbal, the more classic symptoms of abdominal pain, back pain, dysuria, urinary frequency, and new-onset urinary incontinence are predictive of UTI (Shaikh et al., 2007). Successful diagnosis of an infection involves a high degree of suspicion and an understanding of the possible causes of fever, especially in very young children. **UTIs are the most common bacterial infection in children, accounting for 7% of febrile infections in infants and 7.8% of febrile infections in children older than 24 months** (Ishimine, 2007; Shaikh et al., 2008).

Key Points: Diagnosis of Urinary Tract Infection in a Child

- Signs and symptoms of a UTI in young children may be nonspecific.
- UTIs are the most common bacterial infection in a child presenting with a fever.
- Children who appear “toxic” on evaluation require close evaluation because they are likely to have a serious infection.

Definition of a Urinary Tract Infection

What constitutes a “significant” clinical UTI in a child is controversial. Urine has historically been considered sterile, so the presence of bacteria in a urine specimen begins to define whether a UTI is present. If a suprapubic aspiration was performed, then by some criteria recovery of any organisms defines a UTI. For catheterized specimens, recovery of at least 50,000 CFU/mL is required to define a UTI, and 100,000 CFU/mL are required if the specimen was collected via a clean-catch method (Hoberman et al., 1994). In addition, as discussed in the American Academy of Pediatrics (AAP) 2011 UTI clinical practice guideline for children 2 to 24 months, to establish the diagnosis of a UTI, a urinalysis (UA) should suggest infection (pyuria and/or bacteriuria) and identify at least 50,000 CFU/mL of a uropathogen cultured from a urine specimen obtained through urethral catheterization or suprapubic aspiration (Subcommittee on Urinary Tract Infection et al., 2011).

Pathogenesis of Urinary Tract Infection Development in Children

The factors that contribute to UTI development in children are not completely understood. Host features, bacterial characteristics, and immune status contribute to the development of pediatric UTIs. These influences are in a constant state of flux, particularly in children: for instance, immunity and gastrointestinal bacterial colonization are completely different in a newborn as compared with a 6-month-old child.

A typical UTI begins with periurethral contamination by a uropathogen that previously resided in the gastrointestinal tract. After moving to the periurethral environment, the bacteria colonize the urethra and migrate to the bladder. Once bacteria are within the bladder, the bacteria colonize and invade the bladder's superficial umbrella cells. Once within the umbrella cell, an immune response is elucidated. Some bacteria evade the immune response and multiply or form biofilms within the bladder cells. These bacteria may then survive and ascend to the kidneys. Kidney colonization results in bacterial toxin production and host tissue damage. If left untreated, bacteremia may occur (Fig. 25.2).

8 Ascension to the kidneys
7 Epithelial damage by bacterial toxins and proteases
6 Biofilm formation
5 Bacterial multiplication and immune system subversion
4 Neutrophil infiltration
Colonization and invasion of the bladder, mediated by pili and adhesins
3 Inflammation response in the bladder and fibrinogen accumulation in the catheter
1 Colonization of the urethra and mirgation to the bladder
2 Contamination of the periurethral area with a uropathogen from the gut
Fibrinogen
B
Urinary catheter

FIG. 25.2 (A) Uncomplicated urinary tract infections begin when uropathogens that normally reside in the gut colonize the urethra (Step 1). These bacteria then migrate to the bladder (Step 2), where they colonize and invade superficial umbrella cells within the urothelium (Step 3). Innate host inflammatory responses begin to clear bacteria (Step 4). Some bacteria, though, evade the immune system, and these bacteria may then multiply (Step 5) and form a biofilm (Step 6). These bacteria produce toxins and proteases that induce host cell damage (Step 7). They also release nutrients that promote bacterial survival and allow the bacteria to ascend to the kidneys (Step 8). Kidney colonization (Step 9) results in bacterial toxin production and host tissue damage (Step 10). UTIs can ultimately progress to bacteremia if the pathogen crosses the tubular epithelial barrier in the kidneys (Step 11). (B) Uropathogens that cause complicated UTIs follow the same initial steps as those described above, including periurethral colonization (Step 1) and migration to the bladder (Step 2). However, for the pathogens to cause infection, the bladder must be compromised. The most common cause of a compromised bladder is an indwelling urinary catheter. There is a robust immune response induced by catheterization (Step 3), resulting in fibrinogen accumulation along the catheter, providing an ideal environment for the attachment of uropathogens that express fibrinogen-binding proteins. This infection induces neutrophil infiltration (Step 4), but after their initial attachment to the fibrinogen-coated catheters, the bacteria multiply (Step 5), form biofilms (Step 6), promote epithelial damage (Step 7), and can seed infection of the kidneys (Steps 8 and 9), where toxin production induces tissue damage (Step 10). These uropathogens can also progress to bacteremia by crossing the tubular epithelial cell barrier (Step 11). (A, From Flores-Mireles AL, Walker JN, Caparon M, et al.: Urinary tract infections: epidemiology, mechanisms of infection and treatment options. *Nat Reviews. Microbiology* 13:269–284, 2015.)

Bacterial Factors Leading to Pediatric Urinary Tract Infections

Bacteria may be divided into commensal and virulent bacteria. The term *virulence* comes from the Latin word for poisonous, *veneficus*, and is defined as the ability of an organism to cause disease in a host. **Virulent bacteria that cause UTIs are otherwise known as uropathogenic bacteria. Virulent bacteria possess different adaptations and fitness factors that allow them to subvert or hijack host defenses and reside in an environment where they would not normally reside** (Johnson, 1991; Stapleton, 2014). These virulence mechanisms allow the bacteria to attach initially to urogenital mucosal surfaces and then to interact with these tissues by setting off cascades of signaling and other immunologic response events and subsequently invade the bladder (Stapleton, 2014). **Commensal bacteria may also cause UTIs, but commensals are defined by lacking the virulent traits that would allow bacteria to subvert a host's immune defenses.**

Escherichia coli is the most commonly studied UTI-causing organism because it is by far the most common bacterial UTI pathogen. Of the UTIs caused by *E. coli*, 80% are triggered by uropathogenic (virulent) *E. coli* (UPEC), whereas 20% of the *E. coli* causing UTIs are classified as commensal organisms (Bien et al., 2012; Krieger, 2002). This reflects the importance of virulence factors in UTI development. **Virulence factors include properties that improve bacterial adherence to uroepithelial cells, properties that allow bacterial nourishment in otherwise adverse environments, properties that protect bacteria from the host's immune response, and toxins that allow bacteria to invade host cells** (Fig. 25.3).

Bacterial Fimbriae

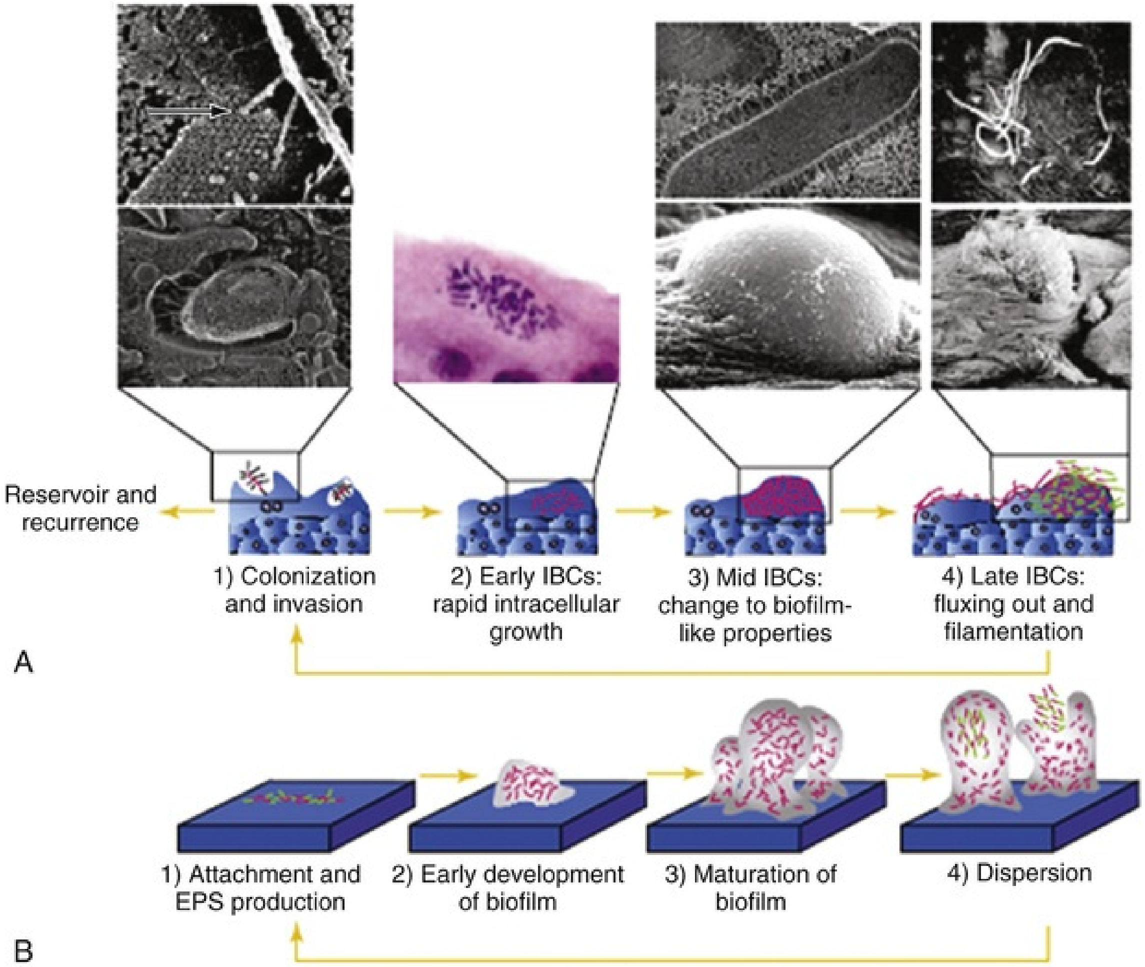
Bacterial adherence is perhaps the best understood and is one of the most studied virulence traits. Once the bacteria are within the bladder, the bacteria must adhere to the bladder epithelium to cause a UTI. **Adherence is considered the first step in UTI pathogenesis with special bacterial structures called *adhesins* mediating this process** (Guyer et al., 2001; Johnson and Stell, 2000; Johnson et al., 2001; Schilling et al., 2001; Wullt et al., 2001). These adhesins are also known as pili or F antigens, and they are filamentous appendages that project from the bacterial cells. Many gram-negative pathogenic bacteria, including *E. coli*, *Klebsiella*, *Proteus*, *Pseudomonas*, *Haemophilus*, *Salmonella*, and *Yersinia*, express a large family of adhesive fibers called chaperone-usher pathway (CUP) pili (Waksman and Hultgren, 2009; Wurpel et al., 2013). Thirty-eight distinct CUP pilus operons have been identified in *E. coli* genomes, and a single UPEC strain can encode more than 12 different CUP pili (Wurpel et al., 2013). Type 1 pili and pyelonephritis-associated (P) pili are the best characterized CUP pili. Type 1 pili are essential for colonization and invasion within the bladder uroepithelial cells (Hadjifrangiskou et al., 2012).

Pili can be classified into mannose sensitive, which is more common, or mannose resistant (Krieger, 2002). The most common mannose-sensitive adhesin is the type 1 pili. Adherence of this fimbriae is blocked by solutions of D-mannose and by concanavalin A (Johnson, 1991). Receptors for type 1 fimbriae are found in the muscular layers but not the epithelium of the human bladder, ureteral epithelium, and kidney cell lines (Fujita et al., 1989; Korhonen et al., 1981; Virkola et al., 1988). Strains of *E. coli*, expressing mannose-sensitive adhesins alone, with no mannose-resistant adhesins, are more commonly associated with patients with clinical symptoms of cystitis and/or asymptomatic bacteriuria (ASB) rather than pyelonephritis, suggesting that type 1 fimbriae play a more important role in the colonization and/or infection of the bladder versus contributing to clinical symptoms of pyelonephritis (Brooks et al., 1981; Gander et al., 1985; Latham and Stamm, 1984).

Another mannose-resistant adhesin is the P pili. These fimbriae were discovered to bind to and agglutinate erythrocytes of the P blood group (Kallenius et al., 1980a, 1980b). The binding site for this adhesin appears to be α-galactose-(1-4), a digalactoside in neutral glycosphingolipids found on epithelial cells and red blood cells. The different P blood group antigens and phenotypes that would bind these fimbriae are found in up to 75% of the population (Johnson, 1991). Binding sites have been identified in the human kidney and bladder, and **isolates expressing P fimbriae have been identified in up to 70% of strains causing clinical symptoms of pyelonephritis** (Johnson, 1991).

After bacterial adherence, a signal transduction cascade results in the uptake of bacteria by the bladder's superficial umbrella cells (Fig. 25.4; Kau et al., 2005; Martinez, 2000). These bacteria enter the bladder's epithelial cells, resulting in the formation of intracellular bacterial communities (IBCs) (Anderson et al., 2003). Typically, an innate defense expulsion defends the urothelium from bacterial invasion. This expulsion mechanism depends on Toll-like receptor 4 (TLR4). However, upon attachment to TLR4, UPEC, through the release of lipopolysaccharide (LPS), stimulates the release of adenylyl cyclase to produce cyclic antimicrobial peptides (AMPs), which induces exocytosis of UPEC into the apical plasma membrane of the bladder's umbrella cells (Song et al., 2009).

Invasion into the bladder urothelium allows UPEC to subvert certain host defenses and certain antibiotic treatments. During the formation of these IBCs, these normally fast-growing bacteria begin to grow at a slower rate until they eventually multiply to fill most of the umbrella cell's cytoplasm (Kau et al., 2005). Eventually the bacteria within the IBCs flux out of the host cell, which may allow bacteria to spread within the urinary tract. The bacteria may then re-enter the bladder epithelial cell and form a quiescent intracellular reservoir (QIR) within the underlying transitional cells. QIRs typically contain only 4 to 10 nonreplicating bacteria, which can remain viable for months, and when reactivated, they serve as seeds by releasing bacteria into the bladder lumen during uroepithelial turnover and result in reinitiation of another UTI (Justice et al., 2004).



Reservoir and recurrence
1) Colonization and invasion
2) Early IBCs: rapid intracellular growth
3) Mid IBCs: change to biofilm-like properties
4) Late IBCs: fluxing out and filamentation

FIG. 25.4 (A) Stages of bacterial invasion of uropathogenic *Escherichia coli* attaching to uroepithelial cell and subsequent formation of pod and dispersion. (B) The similar stages compared with previously known biofilm formation on inert surfaces such as urethral catheters. *EPS,* Extracellular polymeric substances; *IBCs,* intracellular bacterial communities. (From Kau A, Hunstad D, Hultgren SJ: Interaction of uropathogenic *Escherichia coli* with host uroepithelium. *Curr Opin Microbiol* 8:54, 2005.)

Aerobactin

All living cells, including bacteria, need iron. *E. coli* uses iron for oxygen storage and transport, DNA synthesis, electron transport, and metabolism of peroxides (Bagg and Neilands, 1987). As part of the host's response to infection, the amount of available iron is reduced to the invading pathogen by decreasing intestinal absorption, synthesizing additional iron-binding proteins, and shifting iron from the plasma pool into intracellular storage (Johnson, 1991). Therefore *E. coli* face a considerable challenge in acquiring and meeting their iron needs during an infection. The siderophore aerobactin extracts iron from host iron-binding proteins and then delivers the iron directly to bacterial iron centers (Carbonetti et al., 1986; de Lorenzo and Neilands, 1986; Williams and Carbonetti, 1986). Bacterial strains with the aerobactin system have a growth advantage in low iron conditions, including the serum and dilute urine.

Hemolysin

The cytolytic protein secreted by most hemolytic *E. coli* is known as alpha hemolysin (Cavalieri et al., 1984). Alpha hemolysin lyses erythrocytes of all mammals and is also toxic to a wide range of host cells contributing to inflammation, tissue injury, and impaired host defenses (Johnson, 1991). In human UTIs, hemolysin production is most common in bacterial strains from patients suffering pyelonephritis as compared with patients with cystitis symptoms.

Capsular Polysaccharide

Capsular polysaccharides, of which *E. coli* has more than 80 types, are linear polymers that coat the bacterial cell, interfering with antigen detection and protecting the cell from host defense detection (Jorgensen et al., 1976). **The capsules of most uropathic *E. coli* are composed of group II polysaccharides and are otherwise known as K antigens.** Encapsulated K bacterial strains are less well phagocytosed and also have anticomplementary activities, as compared with nonencapsulated strains, which leads to impaired bacterial clearance and complement activation (Harber et al., 1986; Howard and Glynn, 1971). The degree of host defense impairment tends to be proportional to the amount of polysaccharide (Howard and Glynn, 1971). These encapsulated strains are commonly associated with pyelonephritic UTIs rather than cystitis (Johnson, 1991).

Biofilm Formation

Uropathogens may also form biofilms to allow bacterial persistence and recurrent UTIs. Bacterial extracellular DNA, exopolysaccharides, pili, flagella, and other adhesions create a scaffold, which results in the formation of a biofilm. Biofilms create a multicellular bacterial community that is protected from immune responses and antimicrobial treatments. In addition, biofilms provide a physical barrier to antibiotic entry (Kostakioti et al., 2013). UPEC form biofilm-like IBCs within bladder urothelial cells, protecting the bacteria from neutrophils, antibiotics, and other stress (Anderson et al., 2003).

Key Points: Bacterial Factors

- UTI-causing bacteria may be subdivided into commensal and virulent types; although both cause UTI, virulent organisms cause the majority of UTIs.
- Virulent bacteria possess different adaptations and fitness factors that allow them to subvert or hijack host defenses and reside in an environment where they would not normally preside.
- Bacteria have a multitude of virulence factors, including properties that improve bacterial adherence to uroepithelial cells, properties that allow bacterial nourishment in otherwise adverse environments, properties that protect bacteria from the host's immune response, and toxins that allow bacteria to invade host cells.

Host Risk Factors Leading to Pediatric Urinary Tract Infections

Host factors that seem to affect the incidence of UTI development in children are associated with age, genetics, gender, and race and anatomic, functional, and behavioral features.

Gender and Age

The only time that UTIs are more prevalent in boys than in girls is at an age younger than 1 year. At all other ages, even among the elderly, UTIs are far more prevalent in females than in males (Shortliffe and McCue, 2002). About 2.7% of boys, compared with 0.7% of girls, experience a UTI during the first year of life (Winberg et al., 1975). After 1 year of life, the incidence of UTI development drops to 0.03% to 0.2% in males and increases to 1% to 3% in females (Foxman, 2002). **It has been estimated that 7% of girls and 2% of boys experience a UTI by the age of 6 years** (Marild, 1998).

UTIs are common in febrile children, with an incidence of 3% to 5%; however, the risk is greater in girls than in boys after 2 months of age. When evaluating children aged 2 months to 2 years, girls presenting with a fever have a 2.27 greater risk of being diagnosed with a UTI as compared to boys (American Academy of Pediatrics, 1999). In older children, especially in sexually active teenagers, there is also a female predominance of UTIs (Ma and Shortliffe, 2004).

Race

UTIs occur in all races, but they appear more commonly in Caucasian girls compared with girls of other races (Bachur and Harper, 2001; Keeton and Hillis, 1975; Shaw and Gorelick, 1999; Shaw et al., 1998). Several studies have shown that African-Americans have fewer UTIs, have lower rates of vesicoureteral reflux (VUR), and may be less likely to develop reflux nephropathy as compared with Caucasians and Hispanics (Hoberman and Wald, 1997; Kunin, 1968; Lohr et al., 1994; Pinto, 2004).

Genetics

Although certain individuals appear to be more prone to developing UTIs, no specific genes have been identified that are linked to developing these infections. Some observations on the occurrence of UTIs, however, lend evidence that there may be a genetic component to UTI development. Children with a history of VUR are still commonly susceptible to UTI development after their reflux resolves (Beetz et al., 2002; Mansfield et al., 1995). In addition, sisters of patients with recurrent UTIs have higher rates of significant bacteriuria compared with the general population (Stauffer et al., 2004). Moreover, the two greatest risk factors for women ages 18 to 30 years to develop recurrent UTIs include age at first infection and a mother with a history of UTIs (Scholes et al., 2000).

As previously discussed, P fimbriae are a common virulence factor identified on UPEC. At the time of this adhesin's discovery, glycolipids characterizing the P blood group antigens were found on host uroepithelial cells, acting as bacterial receptors. Because it was suspected that individuals with this P blood group phenotype would be more susceptible to UTI development, children with recurrent UTIs were tested for this phenotype. A study by Lomberg et al. (1983) identified that 97% of girls with recurrent pyelonephritis expressed the P1 blood group phenotype in comparison with 75% of controls without UTI.

Other blood group antigens expressed on the urothelial surface also appear to influence UTI susceptibility. These include the ABO, Lewis, and secretor phenotypes. Adult women with Le (a−b−) and Le (a+b+) blood phenotypes are three times as likely to have recurrent UTIs compared with women with the Le (a−b+) phenotype (Sheinfeld et al., 1989). In addition, Jantausch et al. (1994) identified that in children with a history of UTIs, the frequency of Le (a−b−) is also increased. In addition, the nonsecretor phenotype of ABH blood group antigens (ABH Ag) has been identified as associated with renal scars seen on ^{99m}Tc-dimercaptosuccinic acid (DMSA) scans in children with VUR and UTIs (Kanematsu et al., 2005).

Circumcision

Multiple studies demonstrate that circumcision reduces the rate of UTI development in the first 6 months of life by almost 10-fold (Roberts, 1986; Schoen et al., 2000; Wiswell et al., 1987;). This risk appears to correlate with a period during the first 6 months of life when there is an increased amount of uropathogenic bacteria colonizing the prepuce. This colonization appears to decrease and resolve by 5 years of age (Glennon et al., 1988; Wiswell et al., 1988). In a retrospective review, Wiswell and Roscelli (1986) examined the incidence of UTIs diagnosed by catheterization or suprapubic aspirate (SPA) in more than 200,000 males born in US Army hospitals between 1974 and 1983. They found the UTI incidence in circumcised males was 0.11%, whereas the incidence of infection in uncircumcised males was 1.12% compared with an incidence of 0.57% in female children during this study period.

These findings have led to controversy regarding the advantages and disadvantages of routine circumcision in boys. The American Academy of Pediatrics (AAP) Task Force on Circumcision (2012), after weighing the risks and benefits of circumcision in boys (including the prevention of UTIs in neonates), stated that the health benefits of newborn male circumcision outweigh the risks. Although the AAP could not justify routine circumcision in all males, it concluded that the benefits of circumcision are great enough to justify access to this procedure to families choosing it and to warrant third-party payment for the procedure. **However, the question of whether circumcision actually prevents infections later in life continues to be debated in the literature.** Using case-control methods, Singh-Grewal et al. (2005) identified that circumcision continues to decrease the rate of UTI development before and after 1 year of age. The degree of risk reduction, however, is dependent on the patient. In a meta-analysis, Singh-Grewal et al. (2005) identified that normal, healthy boys have a 0.5% to 1% risk of developing a UTI, and they calculated that approximately 111 healthy boys would need to be circumcised to prevent one UTI. Boys who have a history of recurrent UTIs and those who have high-grade VUR have a 10% and 30% risk of UTI recurrence, respectively (Singh-Grewal et al., 2005). Further, the number of boys who would need to undergo circumcision in these high-risk groups to prevent a UTI is 11 boys with a history of recurrent UTIs and 4 boys with a history of high-grade VUR (Singh-Grewal et al., 2005).

Fecal and Perineal Bacterial Colonization

The majority of bacteria causing UTIs enter the bladder via the fecal-perineal-urethral route, whereby bacteria that colonize the gut, perineum, and periurethral area ascend via a retrograde fashion into the lower urinary tract (Pfau and Sacks, 1981; Stamey and Sexton, 1975; Yamamoto et al., 1997). **In women who suffer recurrent UTIs, studies demonstrate that the majority of these reinfections are caused by the same strain of UPEC that persists in the fecal microbiota for 12 or more months and circulates through the fecal and vaginal reservoirs to cause recurrent infections** (Czaja et al., 2009; Hooton, 2001; Russo et al., 1995).

Studies also demonstrate that women who suffer recurrent UTIs have increased vaginal and periurethral colonization with enteric organisms with concomitant loss of normally predominant and protective vaginal lactobacilli (Gupta et al., 1998; Hooton et al., 1994). **Clinical studies show that women lacking vaginal lactobacilli are at increased risk for vaginal colonization with *E. coli*.** Exposure to antibiotics, especially trimethoprim-sulfamethoxazole (TMP-SMX), may eradicate these presumably protective lactobacilli (Stapleton, 2014). Whether a similar mechanism predisposes to UTI in children is unknown. However, Hansson et al. (1989) showed that treatment of schoolgirls for nonurologic infections, usually otitis media, resulted in colonization and bacteriuria with organisms likely to cause a symptomatic infection.

In addition, new data suggest that a microbiome exists with the urine. Until recently, urine within individuals not suffering a UTI has long been considered sterile. However, through the use of 16S RNA gene sequencing, urine within healthy individuals has been found to contain extensive numbers of bacteria that are not cultivated using standard routine microbiology laboratory testing (Lewis et al., 2013; Nelson et al., 2010; Siddiqui et al., 2011; Wolfe et al., 2012). Lewis et al. studied urine from asymptomatic adults 26 to 90 years of age, using clean catch urine samples. They found that samples from females had a more heterogeneous mix of bacteria genera as compared with samples obtained from adult males. Analysis of the specimens found that females generally had bacteria from the phyla Actinobacteria and Bacteroidetes. In addition, the bacteria identified appeared to fluctuate between the different age groups studied (Lewis et al., 2013).

The idea in identifying a urinary microbiome is that, like other environments within the human body such as the gut, resident microbiota maintains a symbiotic relationship resulting in normal urinary health, including metabolic and trophic functions as well as providing a protective barrier against urinary pathogens. Wolfe et al. (2012) examined the urinary microbiome in women suffering from urge urinary incontinence and compared that with the urine in asymptomatic adult women. Using 16S rRNA gene sequencing in urine collected from transurethral catheterization, they identified that the urinary microbiome differed between these two cohorts. These data suggest that the urinary microbiome may account for common urinary symptoms seen in adult women. Although studies have been performed in adults, it is reasonable that if a urinary microbiome exists, it begins to take shape in infancy and childhood. Within the gut, the intestinal microbiome undergoes dynamic changes during development, with the most dramatic changes in composition believed to occur throughout infancy and childhood (Palmer et al., 2007; Tiihonen et al., 2010). As in the gastrointestinal tract, a better understanding of any developing pediatric urinary microbiome may allow for a better understanding of urologic disease and symptoms in children and adults.

Anatomic Abnormalities

Clearly, anatomic abnormalities of a child's genitourinary system may lead to UTI development. Infections associated with urinary tract malformation usually appear before 5 years of age (Chang and Shortliffe, 2006). It is important to detect these abnormalities because many may be surgically correctible, and persistence of these abnormalities may lead to renal damage and/or recurrent infections. Possible anatomic abnormalities include hydronephrosis, ureteropelvic or ureterovesical junction obstruction, VUR, infection stones, infected nonfunctional renal segments, and infected necrotic papillae.

Given the role that anatomic abnormalities play in pediatric UTI development, the AAP continues to recommend that a renal and bladder ultrasound (RBUS) be performed on all children aged 2 to 24 months after they have experienced their first febrile UTI (Subcommittee on Urinary Tract Infection et al., 2011).

Vesicoureteral Reflux

The role that VUR plays in UTI development and the controversies surrounding it are discussed in greater detail later in this chapter and in Chapter 29. VUR has been identified in 1% to 2% of all newborns, but it is found in 25% to 40% of children after their first episode of UTI (Greenfield and Wan, 1996; Hellerstein, 1995). **Although VUR may be present in a child who has suffered a pyelonephritic infection, the majority of children who have suffered from pyelonephritis do not have VUR.** Rushton and Majd found that in children suffering DMSA-proven pyelonephritis, only 37% were shown to have VUR (Rushton et al., 1992). Kidneys associated with higher-grade VUR (grades III–IV), however, were twice as likely to exhibit pyelonephritic changes on DMSA scan (Rushton et al., 1992). The role that VUR plays in UTI development is complex and not completely understood. Variables such as reflux grade and early onset of reflux during bladder filling, patient age, gender of the child, and presence of bowel and bladder dysfunction most likely contribute to UTI development in the presence of VUR.

Sexual Activity

Previous studies have shown that sexual activity increases the risk of UTI development. Kunin (1968) demonstrated that sexually active females suffer more UTIs than sexually inactive females. This finding has prompted some to suggest that UTI may be used as a marker of teenage sexual activity (Nguyen and Weir, 2002). However, this relationship remains poorly defined.

Bladder and Bowel Dysfunction

Bladder and bowel dysfunction, also known as dysfunctional elimination syndrome, is known to contribute to pediatric UTI and VUR. Koff et al. (1998) originally coined the term *dysfunctional elimination syndrome,* which defined children who suffered from infrequent voiding, incomplete bladder emptying, constipation, and/or bladder overactivity. Generally, in addressing children with bladder dysfunction, there are two different entities: (1) overactive bladder and (2) dysfunctional voiding. Dysfunctional voiding terminology is used to describe children with no neurologic issues who exhibit increased activity of their pelvic floor during voiding (Sillen, 2008). Overactive bladder is defined as urinary urgency with or without urge incontinence, usually with frequency and nocturia (Wein and Rovner, 2002). Children suffering from dysfunctional elimination commonly are seen for evaluation of recurrent UTIs (with or without fever), daytime or nighttime urinary incontinence, urinary urgency, urinary frequency, constipation, and/or encopresis.

Children suffering from bladder dysfunction are relatively common. In a study of more than 3500 school-age children, Hellström et al. (1990) found that 6% of girls and 3.7% of boys had daytime urinary incontinence, and more than 8% of the girls showed a history of UTI. Another population-based study examined 1127 children aged 6 to 9 years and found that 29% reported at least one symptom suggestive of bladder dysfunction. Of these children, 9.4% of the girls and 2.8% of the boys had a reported history of a previous UTI (Hansen et al., 1997).

Treatment of a child's bladder and bowel issues reduces recurrent UTIs and improves VUR resolution. Treating children suffering from bladder overactivity with anticholinergics alone resulted in VUR resolution or improvement in 44% to 79% of children (Homsy et al., 1985; Koff and Murtagh, 1983; Scholtmeijer and Nijman, 1994). Treatment of children suffering from dysfunctional voiding with biofeedback resulted in VUR resolution in 55% to 63% of cases and improvement in VUR grade after 1 year of therapy (Kibar et al., 2007; Palmer et al., 2002). Treating bladder dysfunction improves a child's incontinence and reduces the risk of UTI development. Treatment of constipation also improves daytime and nighttime urinary incontinence and helps reduce the incidence of recurrent UTIs. In a study by Loening-Baucke (1997), 234 patients were treated for constipation. At baseline, 46% of these patients suffered from either daytime and/or nighttime urinary incontinence, whereas 11% had suffered at least one UTI. The UTIs were more common in constipated girls compared with constipated boys. Follow-up at least 12 months after starting constipation therapies showed that constipation was successfully relieved in 52% of the children. Relief of constipation resulted in the disappearance of daytime urinary incontinence in 89% and enuresis in 63%, and disappearance of all UTIs in all patients who were without any genitourinary tract anatomic abnormalities.

Neurogenic Bladder

Children with neurogenic bladders and elevated bladder storage pressures risk developing hydronephrosis and renal damage from the increased bladder pressure. In addition to this increased pressure, the physiologic effects of UTI have also been demonstrated to increase intrarenal pelvic pressures and to contribute to an even greater likelihood of renal damage in these individuals (Hansen et al., 2003). When left untreated, children with neurogenic bladders that fill or empty at abnormally high pressures appear to be at higher risk of developing UTIs and renal damage, possibly because of their inability to clear the bacteria spontaneously. Clean intermittent catheterizations facilitate the emptying of the bladders of patients with neurogenic bladder and lower chronic bladder distention and bladder pressure. **Multiple studies demonstrate that 40% to 80% of individuals who intermittently catheterize develop chronic bacteriuria and/or pyuria and most are asymptomatic. Importantly, this catheter-associated ASB appears to lack morbidity most of the time** (de la Hunt et al., 1989; Geraniotis et al., 1988; Gribble and Puterman, 1993; Johnson et al., 1994; Joseph et al., 1989; Schlager et al., 1995). **Ottolini et al.** (1995) **concluded that in the absence of VUR, ASB in patients managed with clean intermittent catheterization is not a significant risk factor for renal damage and does not require antibiotic therapy. Furthermore, stopping prophylactic antibiotic in children with spina bifida is associated with reduced bacterial resistance** (Zegers et al., 2017). In addition, even though most of these children have urine colonized with bacteria, most can undergo urodynamic studies without the need for prophylactic antibiotics (Shekarriz et al., 1999).

Some clinicians prescribe daily prophylactic antibiotics for children who perform chronic clean intermittent catheterization. This practice may delay or decrease bacteriuria in the short term, but in the long term, these prophylactic antibiotics have not been shown to be beneficial and instead may lead to the development of bacterial resistance (Clarke et al., 2005; Johnson et al., 1994). Studies have also been performed evaluating the use of different catheters and their effect on UTI development. **The use of sterile versus nonsterile, single versus multiuse, and lubricated versus nonlubricated catheters have shown no benefit in reducing the risk of UTI development** (Kiddo et al., 2015; Moore et al., 2007; Schlager et al., 1995). Bakke and Vollset (1993) identified that risk factors for UTI development in men and women treated with intermittent catheterization included high mean catheterization volume in women and low frequency of catheterization in men. In addition, they found that patients managed with prophylactic antibiotics were less prone to developing bacteriuria but were more prone to developing clinical UTIs. These findings point toward the role that timely, scheduled catheterizations play in preventing UTIs in those patients managed with clean intermittent catheterization.

Iatrogenic Factors

Catheter-associated UTI (CAUTI) is the most common nosocomial infection, accounting for more than 1 million cases each year in US hospitals and nursing homes (Tambyah and Maki, 2000). **The risk of UTI increases with the duration that the catheter is in place, and the overall incidence of bacteriuria is 8% and ranges from 3% to 10% per day** (Sedor and Mulholland, 1999). In children, nosocomial UTIs account for 6% to 18% of nosocomial infections on pediatric hospital services (Ford-Jones et al., 1989; Lohr et al., 1989). Nosocomial UTIs typically necessitate one extra hospital day per patient or nearly 1 million extra hospital days annually in the United States (Foxman, 2002).

CAUTI has been a prominent target for prevention and intervention. Over a 10-year period from 2001 to 2010, one study found that 3.8 million of 70.4 million catheterized adults developed a CAUTI (Daniels et al., 2014). Over this time, as the impetus to prevent CAUTIs has become realized, the CAUTI incidence rate has decreased from 9.4 cases per 100 catheterizations in 2001 to 5.3 cases per 100 catheterizations in 2010. Mortality from CAUTIs has also declined during this time from 5.4% in 2001 to 3.7% in 2010. Identified risk factors in children include duration of catheterization, a child with contact precautions, and a history of prior catheterization (Lee et al., 2016). **The best way to avoid the morbidity of CAUTI and its related cost is the judicious use of urinary catheters and the removal of urethral catheters in hospitalized patients as soon as they are no longer medically necessary.** In the most recent Healthcare Infection Control Practices Advisory Committee (HICPAC) guidelines, HICPAC notes that catheters should be placed in patients only as a necessity, rather than a convenience (Gould et al., 2009). In addition, HICPAC recommends the consideration of the use of alternatives to indwelling catheters when considered appropriate. These alternatives include the use of external catheters such as a condom-catheter and intermittent catheterization.

Immune Status

Generally, UTIs in young, healthy women are benign conditions with no long-term effects. In contrast, UTIs in young children and geriatric adults seem to be more complicated, with increased morbidity and long-term consequences (Shortliffe and McCue, 2002). Although this contrasting paradigm is incompletely understood, we know that the immune system is diminished at either end of the age spectrum, which may make younger and older individuals more susceptible to urinary infections. Clearly, the first few months of life appear to be the time of greatest risk for the development of UTI (Chang and Shortliffe, 2006). This increased susceptibility may in part be a result of an immature immune system. Serum IgG is lowest from age 1 to 3 months; serum IgA is also found in lower concentrations during the first several months of life and is known to be absent or almost absent along the urothelium during this time (Fliedner et al., 1986; Svanborg Eden et al., 1985; Yoder and Polin, 1986). A discussion of the role that one's immune system may play in UTI development should include the role that a strengthened immune system can play in UTI prevention. Based on these thoughts, there have been attempts to develop UTI vaccines. Since the mid-1990s, several vaccine approaches have been explored, including the use of heat-killed whole bacteria, bacterial cell extracts, and purified UPEC-associated virulence factors as antigens (Barber et al., 2013).

Because adherence is a key factor in UTI pathogenesis, one strategy for the development of vaccine therapy has been to target CUP pili. Vaccination with whole pili has not been effective in generating an antibody response that can protect against UTI development. However, adhesion-based vaccines have been shown to be effective at preventing host-pathogen interactions, thus preventing UTI establishment (Langermann et al., 2000; Mushtaq et al., 2013; Roberts et al., 2004; Savar et al., 2014). Most of these vaccines have been tested in animal models, but in January 2014 a Phase I clinical trial began to evaluate the efficacy of a FimC-FimH vaccine using a synthetic analogue of monophosphoryl lipid A as the adjuvant. Pathogenic UTI-causing bacteria rely on iron-chelating molecules and receptors that allow them to scavenge essential iron from the host (Wiles et al., 2008). The use of purified bacterial iron receptor proteins for vaccination has shown mixed results. Two iron receptors tested as vaccines in mice, IreA and LutA, provided protection against cystitis, whereas vaccination with another iron receptor, Hma, has demonstrated protection against pyelonephritis but not cystitis (Alteri et al., 2009).

These preliminary studies highlight how the focus on different virulence factors may serve as valuable vaccination candidates to prevent UTI from developing. However, similar to our current experience with anticancer chemotherapeutics, we must remember that the use of such factors in vaccine target development may result in inadvertent effects on members of the endogenous microfloras that naturally colonize our bodies that help prevent pathologic UTIs (Barber et al., 2013). Certain delivery methods and other adjuvants may be used in the future to prevent such side effects, and certainly such therapeutics may be useful for individuals susceptible to UTI development, whereas in others the costs and risks may not warrant vaccination.

Key Points: Host Risk Factors

- A multitude of host factors may make a child more susceptible to UTI development.
- The only time when UTIs are more prevalent in boys than in girls is at less than 1 year of age.
- Circumcision reduces the rate of UTI development in the first 6 months of life by almost 10-fold.
- Dysfunctional elimination syndrome is an important factor contributing to pediatric UTI development, and treatment of a child's bladder and bowel issues reduces recurrent UTIs and improves VUR resolution.
- In the absence of VUR, ASB in patients managed with clean intermittent catheterization is not a significant risk factor for renal damage and does not require antibiotic therapy.
- CAUTI is the most common nosocomial infection, and the majority of these infections may be prevented with the judicious use of indwelling catheters.

Classification of Pediatric Urinary Tract Infections

There are several ways to classify UTIs: complicated versus uncomplicated, upper (pyelonephritis) versus lower (cystitis), and first infection versus recurrent infections. A complicated UTI describes infections in individuals who have anatomic or functional abnormalities or the presence of foreign bodies such as ureteral stents or indwelling urethral catheters. This classification, however, may not be best applied to children because infections in neonates or infants are presumed to be complicated because of the common occurrence of urinary tract anatomic abnormalities and the high risk of morbidity in these young patients (Benador et al., 1997; Smellie et al., 1998).

UTIs are usually classified as involving the upper urinary tracts, based on the patient's clinical symptoms. Children are generally assumed to have pyelonephritis when they have a UTI associated with high fevers, nausea, vomiting, flank pain, or lethargy. On the other hand, cystitis is suspected when the child is afebrile and has only lower urinary tract symptoms, including urinary urgency, frequency or dysuria, malodorous urine, and/or suprapubic tenderness. However, using a child's presenting clinical symptoms to classify UTIs into lower and upper urinary tract involvement is not 100% accurate. DMSA scans are considered the gold standard for diagnosing a pyelonephritic infection. **Studies using DMSA scans have shown that, although the majority of patients with fever and systemic clinical findings consistent with acute pyelonephritis (APN) have positive renal scans, there is still a high false-positive rate when relying on symptoms alone to distinguish pyelonephritis from cystitis. Rushton and Majd** (1992) **and Tappin et al.** (1989) **demonstrated that in patients with fever and systemic symptoms, only 50% to 66% demonstrated acute inflammatory changes on DMSA scans. In addition, a small subset of patients who present with afebrile, seemingly lower UTIs may have a positive DMSA scan consistent with APN** (Verboven et al., 1990), but this was noted in only 1 of 9 patients. Differentiation of cystitis and pyelonephritis can also be difficult in children based on the nonspecific symptoms that children may exhibit at the time of their infection. This is especially true in infants younger than 90 days, who commonly experience symptoms that are difficult to interpret, such as failure to thrive, diarrhea, irritability, lethargy, malodorous urine, asymptomatic jaundice, oliguria, or polyuria (Chang and Shortliffe, 2006; Garcia and Nager, 2002).

Recurrent UTIs can be further subdivided into unresolved bacteriuria, bacterial persistence, and reinfection. Unresolved bacteriuria is most commonly caused by inadequate bacterial therapy, which could be secondary to noncompliance, antibiotic malabsorption, suboptimal drug metabolism, and resistant uropathogens that were unresponsive to the attempted therapy (Pewitt and Schaffer, 1997). In these instances, repeated directed treatment based on bacterial sensitivities determined by proper urine culture typically results in resolution of the infection.

Bacterial persistence and reinfection occur after sterile urine has been documented after previous UTI therapy. In cases of bacterial persistence, typically the nidus causing the infection has not been eradicated. Usually the same pathogen is documented on urine cultures during subsequent UTI episodes, despite negative cultures after previous antibiotic treatment. The uropathogen typically resides in a location shielded from antimicrobial therapy. Protected sites include anatomic abnormalities, urinary calculi, necrotic papillae, or foreign objects (i.e., urinary catheters, ureteral stents) (Abrahams and Stoller, 2003; Conrad et al., 1991; Kehinde et al., 2004; Richter et al., 2000; Schlager et al., 2001). Identification of the nidus is important, because typically the infection will persist until the source is removed.

Biofilms

Biofilms appear to play a role in bacterial persistence. Biofilms are structured communities of microorganisms encapsulated with a self-developed polymeric matrix and adherent to a living or inert surface (Tenke et al., 2012). **Antibiotics that are usually adept at microbial eradication often are unable to eradicate bacteria within a biofilm.** The failure of antimicrobial agents to treat biofilms has been associated with the following factors: (1) agents often fail to penetrate the full depth of a biofilm, (2) organisms within a biofilm often grow slowly and are resistant to the antibiotics that usually require active growth, (3) antimicrobial-binding proteins are poorly expressed in these biofilm bacteria, (4) bacteria within a biofilm activate many genes that alter the cell envelope, the molecular targets, and the susceptibility to antimicrobial agents, and (5) bacteria in a biofilm can survive in the presence of antimicrobial agents at a concentration 1000 to 1500 times higher than the concentration normally necessary to kill nonbiofilm-associated bacteria in the same species (Tenke et al., 2006).

Formation of biofilms may allow bacteria to exist at a bladder and at a kidney level. After bacteria reach the kidney, they have been shown to adhere to the urothelium and papillae. In animal models, these bacteria can adhere in thin biofilms to the urothelium before invading the renal tissue (Nickel et al., 1994). It has been further shown that antibacterial agents are less effective against bacteria within these renal biofilms (Nickel et al., 1994).

In addition, biofilms have been shown to form in foreign bodies within the genitourinary tract. These foreign bodies include urinary catheters, ureteral stents, and urinary calculi. Organisms have been shown to ascend through urethral catheters via extraluminal and intraluminal routes. Organisms colonizing the external surfaces of catheters seem to originate from either the gastrointestinal tract or the perineum, whereas intraluminal bacteria appear to come from exogenous sources (Tenke et al., 2012). In fact, it has been shown that 68% to 90% of ureteral stents become colonized with bacteria, whereas the rate of bacteriuria in the same patients is only 27% to 30% (Farsi et al., 1995; Reid et al., 1992).

Asymptomatic Bacteriuria

ASB is defined as the presence of two consecutive urine specimens yielding positive cultures ($>10^5$ CFU/mL) of the same uropathogen in a patient who is free of any infectious symptoms (Kass, 1956). It remains unclear why certain individuals with ASB do not develop symptoms, especially because the organisms recovered from their urine are commonly the same as those seen in patients suffering symptomatic UTIs. In fact, the most common organism obtained from these ASB individuals is *E. coli* (Raz, 2003). One possible mechanism is that the organisms infecting these asymptomatic individuals may be less virulent, resulting in colonization rather than infection.

Some have suggested that the term *asymptomatic bacteriuria* is misleading; some studies have shown that ASB is not always asymptomatic. Gaymans et al. (1976) noted that 30% of women in their study who were initially diagnosed with ASB later became symptomatic and required antibiotic therapy. Furthermore, Savage (1975) found that, although 1.6% of schoolgirls studied suffered from ASB, 60% to 70% of these children actually suffered from lower urinary tract symptoms and daytime and nighttime incontinence, which they admitted after careful questioning. Therefore these children with ASB may have actually been symptomatic.

ASB occurs in less than 1% of full-term infants and in 3% of premature infants (Edelmann et al., 1973). The identification of bacteriuria in these otherwise asymptomatic children is important because these young children may have few signs and symptoms in the face of an infection, and ASB may actually be a marker of underlying genitourinary disease. Given these issues, these infants should be treated with antimicrobial therapy and also should be imaged to evaluate for any congenital issues that could be leading to bacterial colonization (Whitworth, 1981). **ASB occurs in 0.8% of preschool girls and even fewer preschool boys** (Siegel et al., 1980). **Children in this age group who are without VUR and/or other genitourinary abnormalities do not require antibiotics to clear their bacteria because they do not appear to be at any risk for recurrent symptomatic infections, renal damage, or impaired renal growth** (Sidor and Resnick, 1983).

The annual incidence of ASB in school-age girls ranges from 1% to 2%, although about 5% of all school-age girls are estimated to have ASB by the age of 15 years (Kunin et al., 1964; Meadow et al., 1969; Savage et al., 1969). In these school-age girls, spontaneous resolution occurred in 50% in one study, although the 50% who cleared their infection were found to harbor ASB 1 year later (Raz, 2003). Of these patients were treated with antibiotics at the time of identifying the ASB, 20% had persistent cure, whereas 80% had recurrence, and some of these recurrent infections were symptomatic. Girls at this age who are found to have ASB are at very low risk for developing a decline in their renal function or for developing hypertension (Kunin, 1985; Lindberg et al., 1978). **Because antimicrobial therapy in these individuals is unlikely to prevent later asymptomatic or symptomatic bacteriuria, and untreated individuals appear to be at low risk of developing long-term sequelae related to the bacteriuria, routine antimicrobial therapy is not recommended.** Also, routine prophylactic antibiotics could certainly lead to alteration of their microbiota and increased antibiotic resistance in these individuals.

Screening children for ASB is not cost effective. Kemper and Avner (1992) showed that given the sensitivity and specificity of our screening methods and the prevalence of bacteriuria in asymptomatic children, routine screening would result in 20% false-positives. Because there is no evidence that detection and treatment of children with ASB prevent long-term consequences, they surmised that routine screening is neither cost effective nor warranted.

Bacterial Nephritis

Acute bacterial nephritis occurs as the inflammation from bacterial infection within the kidney begins to spread throughout the kidney in an increasingly suppurative process with heavier leukocytic infiltrate and focal areas of tissue necrosis (Davidson and Talner, 1973). **The advanced generalized form of acute nephritis has been termed *acute bacterial nephritis*, whereas the localized form has been called *acute focal bacterial nephritis* or *lobar nephronia*** (Lee et al., 1980). In these individuals, clinical signs and symptoms of septicemia are often present (Thornbury, 1991). Computed tomography (CT) findings include global renal enlargement, inflammatory changes in the perirenal fat, and thickening of Gerota fascia (Soulen et al., 1989). On contrast images, there may be ill-defined, nonhomogeneous decreased parenchymal enhancement that typically is wedge shaped (Fig. 25.5).

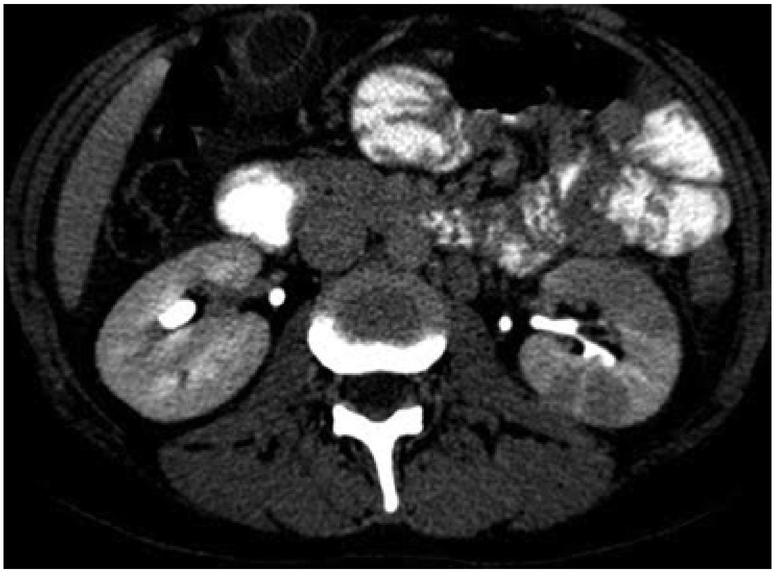

FIG. 25.5 Computed tomography scan demonstrating acute focal pyelonephritis (lobar nephronia).

Pyonephrosis

If purulent exudate from APN accumulates in a dilated renal collecting system, pyonephrosis may occur (Thornbury, 1991). This condition commonly occurs in a hydronephrotic kidney secondary to an obstructed urinary outflow. CT findings typically include an enlarged kidney with a grossly dilated collecting system containing higher-than-usual fluid attenuation.

Acute Renal Abscess

Individuals with a renal abscess often have symptoms similar to patients with pyelonephritis; however, in up to 20% of renal abscess cases, the urine culture may be negative (Thornbury, 1991). This diagnosis is usually based on radiographic findings. Ultrasound can detect an abscess as small as 1 cm and usually appears as a sonolucent area containing low-amplitude echoes (Soulen et al., 1989). CT appears to be the most sensitive and specific imaging modality to use in making the diagnosis of a renal abscess. Associated early CT findings include (1) a well-defined area of low attenuation or decreased enhancement or (2) a striated, wedge-shaped zone of increased or decreased enhancement. In later phases, these areas may coalesce to form a well-defined mass with homogeneous internal attenuation features indicating purulent fluid.

Key Points: Classification

- UTIs may be classified in a variety of ways.
- A UTI is commonly classified as pyelonephritis based on the patient's presenting symptoms, which commonly include fever, flank pain, nausea, and vomiting; however, based on DMSA studies, only 50% to 66% of patients with these symptoms demonstrate acute inflammatory changes on their DMSA scan.
- ASB occurs in 0.8% of preschool girls and even fewer preschool boys. Children in this age group who are without VUR and/or other genitourinary abnormalities do not require antibiotics to clear their bacteria, because they do not appear to be at any risk for recurrent symptomatic infections, renal damage, or impaired renal growth.

Diagnosis of Pediatric Urinary Tract Infection

Defining what constitutes a UTI is surprisingly difficult. Although multiple international guidelines delineate the diagnosis, evaluation, and management of pediatric UTIs, they differ significantly, and a consensus is lacking (Ammenti et al., 2012; Mori et al., 2007; Royal Children's Hospital Melbourne, 2011; Subcommittee on Urinary Tract Infection et al., 2011). At the most basic level, a UTI consists of the invasion of the urinary tract by organisms that result in pathologic changes. These pathologic changes may be caused directly by the infecting organism or by the host response to the infectious agent. In most cases, the individual also suffers symptoms from a UTI. To prove that a patient is experiencing a UTI requires a demonstration of the presence of the infecting organism in the urine and a confirmation that this organism is pathogenic. The presence of the infecting organism is routinely proven by urine culture. The presence of pathology within the urinary tract is frequently inferred by symptoms or by evidence of an immune response identified by urine or blood tests. As discussed in the following sections, controversy exists regarding the best method to obtain urine for analysis and culture as well as regarding the results that can be considered indicative of a true UTI.

Symptoms

The classic symptoms in an adult with a UTI, such as dysuria, frequency, urgency, or suprapubic or flank pain, become progressively more difficult to identify with decreasing age in the pediatric population. Symptoms in infants and young pediatric patients are typically nonspecific and include fever, irritability, poor feeding, jaundice, failure to thrive, vomiting, diarrhea, abdominal distention, or foul-smelling urine (Craig et al., 2010; Rudinsky et al., 2009; White, 2011).

Early after the neonatal period, fever is usually the primary symptom that leads to the diagnosis of a pediatric UTI. The overall prevalence of a UTI in febrile infants with no other identified source of fever is about 5% (Haddon et al., 1999; Hoberman et al., 1993). Fever lasting more than 2 days that is greater than or equal to 38°C without an identified source has been shown to have a positive likelihood ratio of 3.6 (confidence interval [CI] 1.4 to 8.8) of being an occult UTI (Shaikh et al., 2007). This likelihood increases with the duration and height of the fever. Although children with pyelonephritis tend to have fever, as noted previously, this is a nonspecific sign, and children with acute cystitis may also have fever. Older children may complain of more classic symptoms, such as dysuria, incontinence, changes in voiding habits, enuresis, or flank or abdominal pain (Shaikh et al., 2007). However, even when these symptoms are present, they are nonspecific and, in one series of children aged 2 to 19 years with such symptoms, the prevalence of a UTI was only 7.8% (Shaikh et al., 2008). Other causes of lower urinary tract symptoms are frequently seen in patients with bladder and bowel dysfunction or vulvovaginitis. **The lack of specific symptoms produced by a UTI frequently contributes to a lack of prompt diagnosis and treatment; however, the high prevalence of pediatric UTI dictates that it must remain a diagnostic consideration by clinicians caring for children.**

Because the specificity of UTI symptoms is lowest in neonates and young children, as is the difficulty in obtaining urine for analysis and culture in this age group, the AAP 2011 guidelines contained an action statement to assist physicians in determining which febrile children between 2 and 24 months of age should be tested for a UTI (Subcommittee on Urinary Tract Infection et al., 2011). This statement recommends that if the clinician believes a febrile infant with no apparent source of fever is not so ill as to require immediate antimicrobial therapy, then the likelihood of UTI should be assessed. If the likelihood of a UTI is low (<1%), then the infant could be followed without urine testing. If the likelihood is higher, urinary evaluation should be considered. The probability of a UTI in girls has been shown to be greater than or equal to 1%, and the probability is 2% if they had two or more, or three or more, of the following risk factors, respectively: white race, age less than 12 months, temperature greater than or equal to 39°C, fever lasting 2 days or more, or absence of another source of infection (Gorelick and Shaw, 2000). The probability of a UTI in an uncircumcised febrile boy between 2 and 24 months exceeds 1% without any other risk factors. In a circumcised febrile boy, the probability of a UTI has been found to be greater than or equal to 1%, and the probability is 2% if they had three or more of the following risk factors, respectively: nonblack race, temperature greater than or equal to 39°C, fever lasting 2 days or more, or absence of another source of infection (Shaikh et al., 2007).

In addition to the symptoms previously noted, risk factors for UTI should be elicited, such as a history of a previous UTI. Children younger than 6 years with a documented UTI have been noted to have a 12% risk of recurrence per year in a community-based study (Conway et al., 2007). Other risk factors that should be evaluated include the presence of genitourinary anomaly, history of abnormal prenatal or postnatal ultrasounds, family history, and previous genitourinary or gastrointestinal surgery. Such risk factors increase the probability of a UTI and the need for evaluation of a UTI in an unwell child. They may also point to predisposing conditions that require evaluation and treatment. **The possibility of sexually transmitted diseases in older children and adolescents with symptoms of urethritis must be considered. Urethritis can be caused by *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, or *Ureaplasma urealyticum*, as well as routine uropathogens.**

A multicenter diagnostic and prospective observational study (Improving the Diagnosis and Treatment of UTI in Young Children in Primary Care [DUTY]) of 2740 children younger than 5 years of age in the United Kingdom was performed to identify clinical predictors, including signs, symptoms, and urine dipstick results that were most strongly associated with a UTI (Hay et al., 2016). Symptoms and signs that were useful in determining if a urine sample should be collected included pain/crying with passing urine, smelly urine, previous UTI, absence of severe cough, and impression of a severe illness being present. The same signs and symptoms, along with urine dipstick–positive leukocytes, nitrites, and/or blood, were useful in determining if antibiotic treatment was warranted. The authors of the study developed a point system based on these signs, symptoms, and dipstick results and demonstrated it was more accurate than clinical impression alone.

Physical Examination

Specific findings on physical examination in young children are rare and may consist of fever or lethargy. **Even if another source of fever and infection such as otitis, upper respiratory infection, or gastroenteritis has been identified, the clinician must keep in mind that a concurrent UTI has not been excluded.** It is not unusual for the pediatric urologist to see children with a history of recurrent episodes of otitis after their first diagnosed UTI and a subsequent DMSA scan showing renal scars suggesting that the children had multiple previous episodes of pyelonephritis misdiagnosed as otitis. The reduction in risk of a UTI when another infectious source has been identified may be smaller than anticipated, with several studies demonstrating a risk reduction of only about 50% (Bhat et al., 2011). In a study of 2411 febrile 1-year-old children, the prevalence of a UTI without an identified fever source was 5.9%, compared with 2.7% in those with a potential source (Shaw et al., 1998). In this study, the examining clinician incorrectly thought 64% of children with UTI had another source of fever. This highlights the need to **consider the possibility of a UTI in any febrile infant, even if another source has been identified.**

Boys and girls should have an abdominal examination to assess for a palpable abdominal mass that may indicate bladder distention or a flank mass consistent with hydronephrosis. Older children may experience suprapubic, abdominal, or flank tenderness. Costovertebral angle tenderness is suggestive of pyelonephritis. A careful examination of the external genitalia should be performed to rule out trauma, local irritation, urethral meatal stenosis or discharge, phimosis, foreign body, and anatomic abnormalities. Boys should be examined for testicular tenderness, which may be a sign of epididymo-orchitis. The introitus should be inspected in girls for discharge and signs of local irritation, ectopic ureter, or protruding urethral mass such as a prolapsing ureterocele. Examination of the back for signs of spina bifida occulta such as a prominent fat pad or asymmetric gluteal cleft or sacral dimple, along with a neurologic examination, may point to underlying neurologic causes of abnormal bladder function predisposing to UTIs.

Laboratories

Urine Collection Methods

Because of the nonspecific symptoms and signs, the diagnosis of a UTI requires the demonstration of an infectious agent or agents in the urine. In addition, the AAP guidelines also require evidence of pyuria for the diagnosis of a UTI to help distinguish a true infection from ASB or contamination. **Unfortunately, the chance of collecting a contaminated urine specimen increases with the decreasing degree of invasive collecting methods.** Different guidelines suggest different methods of collecting urine specimens. The least invasive method of obtaining a urine specimen consists of affixing a collection bag to the perineum. This method has the highest chance of contamination by perineal and rectal flora, as well as by white blood cells (WBCs) from outside the urinary tract, producing false-positive results. The urine from a collection bag only provides reliable information when the specimen is normal. A clean-catch midstream urine sample is also noninvasive but carries a higher chance of contamination from periurethral tissues than urine collected via more invasive methods including catheterization or SPA. The clean-catch urine is more reliable in an older girl or a circumcised boy or in an uncircumcised boy who will retract his foreskin compared with a younger girl or an uncircumcised boy who cannot retract the foreskin.

For young, non–toilet-trained children younger than 2 years of age, the AAP guidelines recommend either SPA or catheterization. The disadvantages of these methods include their invasiveness and the potential for trauma or infection and the fact that they may not be feasible as a routine procedure in primary care. The guidelines of the National Institute for Health and Care Excellence (NICE), Italian Society of Pediatric Nephrology (ISPN), and Royal Children's Hospital (RCH) Melbourne recommend a clean-catch urine specimen when possible. Compared with SPA, the clean-catch urine for culture has a sensitivity of 75% to 100% and a specificity of 57% to 100% (Bitsori and Galanakis, 2012; Whiting et al., 2006). Compared with SPA, the catheterized urine has a sensitivity of 95% and a specificity of 99% (Roberts, 2012).

Catheter insertion should be performed in a sterile fashion. The use of intraurethral and/or topical lidocaine has been demonstrated effective in reducing discomfort with bladder catheterization (Gerard et al., 2003; Mularoni et al., 2009; Vaughan et al., 2005). Successful catheterization in girls often requires a two-person technique. The labia majora should each be placed on gentle traction outward from the body and slightly lateral to help expose the vaginal and urethral opening to facilitate the correct location for catheter insertion. This method, as opposed to using a single hand and fingers spreading the labia laterally, more routinely exposes the normally recessed urethral opening and the surrounding anatomic landmarks. The exposure with this two-hand technique reduces the temptation to pull the labia too far laterally, which may occur with a single hand. Pulling the labia too far laterally can cause pain, making subsequent catheterization far more difficult and traumatic. After catheter insertion, the first several drops of urine obtained from a catheter should not be collected because they may contain urethral bacterial contamination.

The method of suprapubic aspiration involves prepping the skin and inserting a 22-gauge needle 1 to 2 cm above the pubic bone into the bladder and aspirating the urine into a sterile syringe. The reported success rates of obtaining urine by

SPA are variable and, although not routinely required, ultrasound confirmation of urine in the bladder, as well as guidance during the procedure, have demonstrated improved success rates (Buys et al., 1994; Gochman et al., 1991). Topical or local anesthetic may also be used, but data confirming a significant reduction in discomfort with their use are lacking.

Urinalysis

UA routinely consists of urinary dipstick testing and microscopic examination. A UA specimen should be performed on urine less than 1 hour after voiding if the specimen has been maintained at room temperature or less than 4 hours if refrigerated. Although a urine culture is the gold standard for diagnosis of a UTI, a culture requires at least 18 hours to demonstrate growth and 2 to 3 days to determine the final result and antibiotic susceptibilities. The UA provides rapid information that may be used to determine the likelihood of a UTI and the appropriateness of beginning antibiotic treatment for a presumed UTI. Although threshold values for positive and negative dipstick and microscopic examination results have not been adjusted for urinary specific gravity (i.e., dilution/concentration), it has been demonstrated that the positive and negative likelihood ratios of these results are affected by urine concentration (Chaudhari et al., 2017).

Urine Dipstick Tests

The most frequently used dipstick tests for evaluation of UTI include leukocyte esterase and nitrite. Leukocyte esterase is released from white cells that are broken down in the urine and serves as a marker for pyuria. **The sensitivity of leukocyte esterase for detecting UTI ranges from 47% to 95% in various studies with a summary estimate of 79% (95% CI 73%–84%)** (Hoberman et al., 1994; Williams et al., 2010). **The specificity ranges from 64%–92%, with false-positives resulting from other causes of inflammation or white cells in the urine** (Subcommittee on Urinary Tract Infection et al., 2011). **The summary estimate of leukocyte esterase specificity was 87% (95% CI 79%–91%) in a large meta-analysis by Williams et al.** (2010). The addition of other urinary biomarkers to the UA leukocyte esterase results, including AMPs, human a-defensin 5 (HD5) and human neutrophil peptides (HNP) 1–3, offer the possibility of improved UA specificity (Watson et al., 2016). Although some estimate that the leukocyte esterase test misses more than 20% of children with a

UTI, the AAP guidelines suggest the absence of leukocyte esterase in the urine helps distinguish individuals with ASB from those with a true UTI, because the absence of pyuria in children with a true UTI is rare (Bhat et al., 2011; Subcommittee on Urinary Tract Infection et al., 2011).

Urinary nitrite is reduced from dietary nitrates in the urine by gram-negative enteric bacteria. This conversion requires several hours to occur; thus a first-morning urine has the best sensitivity with this test. Frequent urination, as is often the case in infants and small children, may not permit enough time for the urine in the bladder to undergo significant conversion of nitrates to nitrites and therefore may result in a false-negative nitrite test more frequently than in older children (Mori et al., 2010). A dilute urine may also generate a false-negative test. Other reasons for false-negative tests include infection with gram-positive organisms that do not reduce nitrates. **Because of false-negatives, the sensitivity of the nitrite test is about 50%, with a reported range from 8% to 95%. The specificity, however, is very high, at 98%, with a range from 90% to 100%, meaning a positive nitrite test is very likely to reflect a true UTI.** In the large meta-analysis by Williams et al. (2010) the sensitivity and specificity for nitrites were 49% (95% CI 41%–57%) and 98% (95% CI 96%–99%), respectively.

If either leukocyte esterase or nitrite is positive, the sensitivity and specificity for UTI has been reported to be 88% (95% CI 82%–91%) and 79% (95% CI 69%–87%), respectively (Williams et al., 2010). If either of these tests is positive or the microscopic UA is positive (see following), the sensitivity increases to 99.8% with a specificity of 70% (Subcommittee on Urinary Tract Infection et al., 2011). If both tests are negative, the presence of a UTI is much less likely, with a negative likelihood ratio of 0.22; however, based on the severity of the clinical picture, including a consideration of the patient's age, in many cases the safest course of action may be to continue antibiotics until culture results are available (Perkins et al., 2012). Although not widely used, some have suggested that the addition of the dipstick results for blood and protein to leukocyte esterase and nitrite results improves sensitivity and specificity. Ramlakhan et al. (2011) demonstrated that if a sample was negative for all four of these parameters, the sensitivity for ruling out a UTI was 97.4% (95% CI 91%–99%) and a negative likelihood ratio of 0.10 (95% CI 0.02%–0.39%). They noted the best test for confirming a UTI was a combination of leukocyte esterase and nitrite and blood, with a specificity of 97.1% (95% CI 94%–99%) and positive likelihood ratio of 15.13 (6.99–32.76).

Urine Microscopic Examination

The traditional method of assessing pyuria by microscopy is on a centrifuged urine specimen with a threshold of 5 WBCs per high-power field (HPF); however, a threshold of 10 WBCs/HPF has been considered more reliable to predict UTI in children younger than 2 years old by the NICE, ISPN, and RCH Melbourne guidelines (Bitsori and Galanakis, 2012). Williams et al. (2010) reported the sensitivity and specificity of 5 microscopic WBCs/HPF for determining UTI as 74% (95% CI 67%–80%) and 86% (95% CI 82%–90%), respectively. The true positive rate for 5 WBCs/HPF and for 10 WBCs/HPF has been reported as 67% (range 55%–88%) and 77% (range 57%–92%), respectively. False-positive rates for 5 and 10 WBCs/HPF have been reported as 21% and 11%, respectively (Gorelick and Shaw, 1999). Given the sensitivity and specificity of microscopic pyuria, there does not appear to be an advantage of microscopy for WBCs alone over leukocyte esterase for the determination of UTI, and the additive value of microscopy to dipstick results is questionable (Cantey et al., 2015).

The most reliable rapid test for diagnosing a UTI consists of the microscopic identification of bacteria on unstained and Gram-stained uncentrifuged fresh urine specimens (Gorelick and Shaw, 1999; Williams et al., 2010). The sensitivity and specificity for microscopic bacteria are improved by Gram stain (Subcommittee on Urinary Tract Infection et al., 2011). The sensitivity of microscopic bacteria on Gram-stained samples to determine a UTI is 91% (95% CI 80%–96%) and on unstained samples it is 88% (95% CI 75%–94%). The specificity on stained and unstained samples is excellent at 96% and 92%, respectively; however, routine Gram stain does not appear to enhance the diagnosis of UTI in children undergoing UA (Cantey et al., 2015; Williams et al., 2010). Enhanced UA uses a WBC counting chamber on uncentrifuged urine and uses the microscopy of a Gram-stained urine smear for detection of bacteria. This improves predictive results but requires the availability of specialized equipment and personnel that are not routinely available in many clinical settings.

Urine Culture

A positive urine culture is essential for the diagnosis of a UTI. The definition of what constitutes a true positive urine culture based on the number of colony-forming units per milliliter of urine is debated. As with most tests,

the lower the threshold is set, the higher the likelihood of obtaining false-positive results and overtreating patients who do not have infection. Conversely, setting a higher threshold increases the chance of undertreating patients. Historically, the threshold used to diagnose a positive urine culture was greater than or equal to 10^5 CFU/mL of a uropathogen. However, this value was initially based on morning-voided urine samples in adult women, and this cutoff may not be as applicable in children (Kass, 1962).

Factors that may reduce the concentration of bacteria in the urine of a child with UTI include frequency of urination as well as urine output. At present, there is a lack of uniform agreement on what colony count should be used as the threshold values for the diagnosis of a pediatric UTI. The 2011 AAP guidelines suggest that, in children ages 2 to 24 months, the threshold value of greater than or equal to 10^5 CFU/mL be reduced. These new guidelines recommend that 50,000 CFU/mL, now including the requirement of a positive UA for pyuria from a urine sample obtained by catheterization or SPA, be used for the diagnosis of UTI. Alternatively, the European Association of Urology suggests that 10^4 CFU/mL is indicative of UTI with a midstream specimen if associated with symptoms, but 10^5 should be used if there are no symptoms (Downing et al., 2012).

Other guidelines have taken into consideration the risk of contamination by various methods of urine collection, and their threshold values have been adjusted accordingly. The RCH Melbourne guidelines suggest that any gram-negative bacteria by SPA and greater than 10^3 CFU/mL by catheterization is consistent with UTI. The ISPN guidelines use greater than 10^4 CFU/mL by catheterization for a catheterized specimen and more than 10^5 CFU/mL for a midstream/clean-catch specimen (Bitsori and Galanakis, 2012).

Contamination is more likely in cases with low colony counts. It is also more likely in cultures with heavy, mixed growth of bacteria. In such cultures, however, urologists must consider the possibility of the existence of a true UTI along with a contaminated specimen when making treatment decisions. Contamination is also more likely in cultures growing nonpathogenic organisms. Such organisms include *Lactobacillus*, coagulase-negative staphylococci, *Corynebacterium*, alpha-hemolytic streptococci, and *Candida* (Bhat et al., 2011).

Serum Tests

A variety of different serum and urine tests have been evaluated for their ability to differentiate kidney infection in a child with UTI. When bacteria invade the kidney, Toll-like receptor signaling initiates an immune response involving the production of cytokines and chemokines, and urinary levels of interleukin-6, interleukin-8, and transforming growth factor-β1 may be elevated (Krzemien et al., 2016; Montini et al., 2011). This local response may also be accompanied by a systemic response involving fever, elevated WBC, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and procalcitonin. Fever, ESR, and peripheral WBC count have not been shown to differentiate reliably the upper from the lower UTI (Garin et al., 2007). CRP has reasonable sensitivity but low specificity for diagnosing kidney involvement, limiting its use (Bhat et al., 2011; Garin et al., 2007). Procalcitonin rises in response to bacterial endotoxins, although its exact role in the inflammatory response is unknown. **In a recent meta-analysis, procalcitonin was shown to be a more robust predictor compared with CRP or WBC for selectively identifying children who had APN during the early stages of UTI as well as those with late scarring as identified by DMSA scanning** (Leroy et al., 2013). **The sensitivity and specificity of a procalcitonin level greater than or equal to 0.5 ng/mL for detection of APN were 71% and 72%, respectively, and 70% sensitivity and 50% specificity for late renal scarring.** Although the sensitivity and specificity for procalcitonin appear limited, it is possible that combining this information with other clinical and laboratory data will improve identification of individuals with kidney infection and guide subsequent clinical management, including radiographic imaging (i.e., DMSA or voiding cystourethrogram [VCUG]). Investigation of urinary biomarkers, such as C-megalin, to identify children with renal scars after a febrile UTI is ongoing (Yamanouchi et al., 2017).

Key Points: Symptoms and Laboratory Analysis

- Symptoms of UTI in infants and young pediatric patients are typically nonspecific.
- Even if another source of fever and infection such as otitis, upper respiratory infection, or gastroenteritis has been identified, the clinician must keep in mind that a concurrent UTI has not been excluded.
- Urine from a collection bag only provides reliable information when the specimen is normal because of the high incidence of contamination.

- The guidelines for diagnostic criteria for a UTI vary.
- Leukocyte esterase has a high sensitivity but a lower specificity. Urinary nitrite has a high specificity but lower sensitivity.

Radiographic Imaging

Controversies With Imaging Strategies

As with many of the other aspects related to pediatric UTI, there is a lack of consensus regarding imaging after a first febrile UTI in children. Part of this controversy relates to a lack of evidence supporting the use of routine imaging in decreasing long-term sequelae of kidney infections, including renal scarring, hypertension, and renal insufficiency or failure (Moorthy et al., 2005; Wan et al., 2012; Wennerstrom et al., 2000). Previously, the standard evaluation consisted of an ultrasound and a VCUG. However, despite prevalence rates of VUR of more than 30% in many series of children with a febrile UTI, a lack of proven effectiveness of prophylactic antibiotics in preventing recurrent UTIs or renal scars in children with lower grades of VUR has led many to question the use of obtaining a VCUG in all children after their first UTI (Karmazyn et al., 2017). Recommendations vary significantly between guideline committees and various advocates (Table 25.1). The NICE guidelines recommend routinely obtaining an ultrasound in children less than 6 months old, but these guidelines limit it in those more than 6 months to children with either a recurrent UTI or an atypical UTI as defined by being seriously ill, by poor urine flow, by abdominal or bladder mass, by raised creatinine and septicemia, by failure to respond to treatment within 48 hours, or by infection with a non–*E. coli* organism (NICE, 2013). Conversely, the revised AAP guidelines recommended obtaining a renal ultrasound in all children less than 2 years of age with a febrile UTI, but these guidelines no longer recommend routinely performing a VCUG in these children if the ultrasound is normal (Subcommittee on Urinary Tract Infection et al., 2011). **In a rebuttal to the AAP guidelines, the Section of Urology of the AAP noted that the revised guideline was based on conclusions that were premature and represented a misinterpretation of data and did not agree that a VCUG should not be routinely performed** (Wan et al., 2012)**. Rather, they recommended that a VCUG remain as an accepted option. They noted that some children with VUR, most frequently those with higher-grade VUR, do benefit from early detection and treatment that prevents subsequent kidney infection, damage, and loss of function. Furthermore, the**

RIVUR study demonstrated a 50% reduction in febrile or symptomatic UTIs over 2 years in children with VUR on prophylaxis compared with placebo (Hoberman et al., 2014.)

TABLE 25.1

Summary of the Five Imaging Recommendations

GUIDELINES	ULTRASOUND	VOIDING CYSTOURETHROGRAM	LATE DMSA SCAN
RCH	Yes	If boys <6 mo and/or positive ultrasonography	No
NICE			
<6 mo	Yes	If positive ultrasonography and/or atypical UTI[a]	
≥6 mo	If atypical UTI	If children with risk factors[b]	If atypical UTI[a] If atypical UTI[a]
TDA	No	If positive acute DMSA	If positive acute DMSA
AAP	Yes	If positive ultrasonography	No
ISPN	Yes	If positive ultrasonography and/or children with risk factors[c]	If positive ultrasonography and/or VUR

[a] Seriously ill, poor urine flow, abdominal or bladder mass, raised creatinine, septicemia, failure to respond to correct antibiotic treatment within 48 h, or infection with non–*Escherichia coli* organisms.

[b] Dilation on ultrasonography, poor urine flow, non–*E. coli* infection, or family history of VUR.

[c] Abnormal prenatal ultrasonography of the urinary tract, family history of VUR, septicemia, renal failure, age <6 mo in a male infant, likely noncompliance of the family, abnormal bladder emptying, no clinical response to correct antibiotic treatment within 72 h, or non–*E. coli* infection.

AAP, Academy of Pediatrics; *DMSA,* ^{99m}Tc-dimercaptosuccinic acid; *ISPN,* Italian Society of Pediatric Nephrology; *NICE,* National Institute for Health and Care Excellence; *RCH,* Royal Children's Hospital (Melbourne); *TDA,* top-down approach; *UTI,* urinary tract infection; *VUR,* vesicoureteral reflux.

Data from La Scola C, De Mutiis C, Hewitt IK, et al.: Different guidelines for imaging after first UTI in febrile infants: yield, cost, and radiation. *Pediatrics* 131:e665–671, 2013.

Multiple studies have evaluated the potential sensitivity and specificity of various imaging guidelines after a first febrile UTI with respect to the identification of children with VUR, APN, or renal scars. One review demonstrated that the NICE and AAP protocols would miss 50% and 61% of children with grades III to V VUR and 62% and 100% of renal scars, respectively (La Scola et al., 2013). Another study demonstrated that the NICE protocol did not work as well in boys compared with girls with respect to negative predictive values (Wong et al., 2010). On the other hand, proponents of the NICE or AAP approaches note that significant numbers of children without high-grade VUR were spared the trauma, radiation exposure, and added expense by not undergoing a VCUG or a DMSA scan. In addition, proponents would note that those children possibly benefiting from the diagnosis of higher grades of VUR would be identified after a recurrent UTI and that prompt diagnosis and treatment of that recurrent UTI further minimizes the relatively low chance of renal damage and sequel in these children.

An alternative approach to imaging the febrile child with a UTI has been termed the *top-down approach* (TDA). Those advocating for a TDA recommend obtaining a DMSA scan in children after their first febrile UTI. By subsequently obtaining a VCUG in only those children with an abnormal DMSA scan, this approach may only miss 15% to 30% of children with dilating VUR; however, it does have a lower specificity than some of the other imaging guidelines (Hansson et al., 2004; La Scola et al., 2013; Preda et al., 2007; Tseng et al., 2007). The NICE guidelines recommend DMSA 4 to 6 months after acute infection for children younger than 3 years with atypical or recurrent UTI and for children older than 3 years with recurrent UTI. The AAP guidelines do not recommend routine DMSA.

Currently, it is fair to suppose that all imaging strategies fall short of the ultimate goal of being able to identify and test only those children that will benefit from the results of these tests. In addition, as with all testing, the clinician must ask if the results will alter the management of the child, and if the answer is *no*, then the test should not be ordered.

Ultrasound

Although the usefulness of obtaining an RBUS in all children with a UTI is questioned, the fact that it is noninvasive, free from radiation exposure, and widely available makes its routine use widely accepted for children with a history of UTI. The RBUS is frequently the initial imaging study, and it demonstrates abnormalities in about 15% of infants and young children after their first febrile UTI (Subcommittee on Urinary Tract Infection et al., 2011). It is estimated that 1% to 2% of these children will exhibit an abnormality that requires additional evaluation or treatment (Alon and Ganapathy, 1999;

Hoberman et al., 2003; Montini et al., 2008). In children older than several years, relative indications for obtaining RBUS include recurrent febrile UTIs, failure to respond as expected to antibiotic therapy, hypertension, and a family history of renal or urologic disease.

In addition to demonstrating the size, shape, and presence of both kidneys, ultrasound helps screen for previously undiagnosed congenital abnormalities, urinary tract obstruction, hydronephrosis, stones, pyonephrosis, and fluid collections such as renal or perirenal abscesses. If a child is unusually ill or not responding to treatment as expected, the clinician may want to obtain an ultrasound as soon as possible to rule out these conditions because these conditions would warrant additional urgent interventions. A limitation of obtaining an ultrasound during the acute phase of pyelonephritis is the potential for inflammatory changes and edema to cause false-positive results. The inflammatory changes during the acute phase may cause an overestimation of renal size that may not be reflective of the true baseline size of the kidney. If the infection and changes are localized, as in a case with an acute focal pyelonephritis (lobar nephronia), they may create the appearance of a mass or tumor. In addition, *E. coli* endotoxin may result in renal pelvis dilation that could be confused for hydronephrosis and lead to unnecessary testing (Subcommittee on Urinary Tract Infection et al., 2011).

Multiple studies demonstrate a strong correlation between the relative renal volume determined by ultrasound and the relative renal function determined by renal scintigraphy in children (Adibi et al., 2007; Sargent and Gupta, 1993; Troell et al., 1984, 1988; Weitz et al., 2013). However, the ultrasound has relatively poor sensitivity for identifying renal injury or scars compared with nuclear cortical renal scintigraphy, and it may miss more than 10% of renal scars (Christian et al., 2000; Massanyi et al., 2013; Moorthy et al., 2004). Despite this limitation, ultrasound may be useful in screening the children who would be most likely to benefit by further evaluation with a DMSA scan.

Some authors question the usefulness of obtaining an ultrasound in all children with a febrile UTI. The NICE guidelines do not recommend obtaining an ultrasound in children between 6 months and 3 years of age after the first febrile UTI unless it is atypical. Part of this questioning is related to the limitations of routine ultrasonography. High-resolution ultrasonography has improved the sensitivity of the ultrasound for detection of acute renal involvement (Morin et al., 1999). **It is also widely recognized that renal ultrasound includes a very low sensitivity for the detection of VUR, even**

with high grades of VUR (Juliano et al., 2013; Nepple et al., 2011; Supavekin et al., 2013; Suson and Mathews, 2014). In one large study of children less than 24 months of age after their first febrile UTI, the ultrasound failed to detect 73% of those patients considered to have urologic abnormalities that would require additional surgical or medical interventions (Wong et al., 2010). Others have demonstrated that a normal ultrasound was not associated with a decreased risk of recurrent pyelonephritis (Juliano et al., 2013).

Voiding Cystourethrogram

VCUG may be performed by the instillation of an iodinated contrast medium into the bladder and imaging with fluoroscopy or with the instillation of nuclear imaging agents such as ^{99m}Tc-pertechnetate. **When performed with contrast, the VCUG remains the gold standard imaging technique for the detection and grading of VUR.** Because of the improved anatomic resolution, many prefer to use a contrast VCUG as the initial method of evaluation and reserve the radionuclide cystogram for follow-up imaging. **The contrast VCUG provides additional information aside from grade that may be significant in evaluating and treating a child with a history of UTI. It provides anatomic information about the bladder such as size and shape and the presence of trabeculations or diverticula. The voiding images, which are an essential component of the standard VCUG, provide information about the function of the urinary sphincters as well as any evidence of urethral obstruction.** The images may also be evaluated for the stool pattern that could suggest constipation, which is frequently associated with UTIs and abnormal bladder function. In addition, the images may also demonstrate a spinal defect consistent with spina bifida occulta and may raise the possibility of a tethered spinal cord.

In evaluation of the child with UTI, VCUG may be performed as soon as the urine is sterile and the child is asymptomatic and demonstrating typical voiding (Hoberman and Wald, 1999). A negative VCUG does not completely eliminate the possibility of VUR. One study demonstrated that 30% of patients with a history of VUR and a single negative nuclear VCUG showed positive cystogram results 1 year later (Neel and Shillinger, 2000). A cyclic VCUG, in which the bladder is filled, the child voids, and the bladder is filled a second time and is followed by voiding, increases the sensitivity for VUR detection as well as the detection of an ectopic ureter. To minimize interinstitutional variables in the technical performance of a VCUG, the Sections of Urology and Radiology of the AAP established a standard protocol for the voiding cystourethrography

(Frimberger et al., 2016).

^{99m}Tc-Dimercaptosuccinic Acid

Cortical renal scan with DMSA combined with single-photon emission computed tomography (SPECT) is considered by many as the gold standard for identification of lesions in the renal parenchyma (Craig et al., 2000; De Palma and Manzoni, 2013). DMSA is injected intravenously and is taken up by the kidney, bound to the proximal renal tubular cells, and excreted very slowly in the urine, providing good and stable imaging of the renal cortex. The imaging is obtained 2 to 4 hours after injection. It has been shown with CT that DMSA may miss some lesions of APN; however, there are significant drawbacks to using CT in children with UTI (see following) (Lee et al., 2011). The radiation dose for DMSA scintigraphy has been estimated as 1 mSv (La Scola et al., 2013).

The maximum sensitivity of DMSA for detection of APN is within 1 week from the onset of symptoms (Zhang et al., 2014). **A DMSA within the first 10 days of APN shows abnormal results in 49% to 79% of patients, and this decreased to 30% by 1 month after a UTI** (Supavekin et al., 2013). **Therefore the timing of DMSA for detection of kidney involvement with a UTI significantly affects its sensitivity.** Acute DMSA studies usually demonstrate uptake defects in the cortex. In addition, the overall size of the kidney may appear enlarged because of inflammation and edema. **Assessment of irreversible renal damage and scar should not be performed earlier than 6 months after APN, and some suggest waiting up to 1 to 2 years for resolution of any reversible defects** (De Palma and Manzoni, 2013). Many acute cortical lesions are transient, but about 15% of children with these lesions develop evidence of renal scarring on repeated DMSA (Shaikh et al., 2010). Renal scars appear as regions of decreased uptake in the cortex, but they may be indistinguishable from regions of congenital renal dysplasia that are frequently associated with VUR.

Multiple studies demonstrate that the risk of an abnormal DMSA is increased in patients with dilating grades of VUR compared with those with nondilating or no VUR (Supavekin et al., 2013; Wong et al., 2010; Zhang et al., 2014). The degree of renal scarring has also been demonstrated to be worse with higher grades of VUR (Shaikh et al., 2010; Supavekin et al., 2013). In addition, abnormal DMSA scan has been demonstrated to decrease the likelihood of spontaneous VUR resolution independent of the grade of VUR (Nepple et al., 2008a, 2008b; Sjostrom et al., 2010). Most studies demonstrate that older children have a higher chance of renal cortical defects, which is a finding that is consistent with the cumulative nature of scars.

In addition to DMSA, other renal nuclear agents such as ^{99m}Tc-mercaptoacetyltriglycine (MAG3) may be used. Although it may not provide the level of detailed imaging of the renal cortex obtained with DMSA, it does have some advantages. This scan provides renal cortical imaging as well as imaging of the collecting system, which is useful in assessing obstruction of urinary flow. In a very hydronephrotic kidney, imaging of the collecting system may help reduce false-positive results that would be obtained with a DMSA. Because of its uptake and rapid excretion relative to DMSA, the duration of the study and the radiation dose to most organs, including the bladder and gonads, are reduced (Sfakianakis and Georgiou, 1997).

Computed Tomography

Although CT provides detailed anatomic imaging and excellent sensitivity for determination of kidney involvement with infection, the high degree of radiation, as well as potential problems with contrast media, severely limit any benefit of this imaging modality in a child with a UTI. The mean radiation dose for a pediatric abdominal/pelvic CT is 10 to 15 mSv (Miglioretti et al., 2013). One exception may be a noncontrast CT when there is a high index of suspicion for urolithiasis not identified by ultrasound. In addition, it may be useful for distinguishing inflammatory changes from the tumor at times when the acute ultrasound is suspicious for a renal mass. Typical findings associated with renal infection and inflammation include cortical regions of hypoattenuation, wedge-shaped defects, a loss of the corticomedullary differentiation, and striations. Although a renal abscess may show no function, a similar appearance can occur on the acute scans with an acute focal pyelonephritis, and delayed scans may be required to distinguish these entities.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) provides excellent anatomic and functional renal imaging. However, the expense and potential need for sedation or anesthesia, as well as a limited availability of the procedure, restrict the use of routine MRI in the child with febrile UTI. In addition, there is a risk of nephrogenic systemic fibrosis in some patients with impaired renal function related to paramagnetic contrast media (De Palma and Manzoni, 2013).

Key Points: Radiographic Imaging

- Various conflicting guidelines have been developed for imaging the child with a UTI; however, all fall short of being able to identify and test only those children who will benefit from the results of these tests.
- Ultrasound is noninvasive and free of radiation and is readily available, but it is unreliable at detecting VUR and will also miss some renal scars.
- VCUG is the most reliable method of detecting and grading VUR as well as imaging the bladder and urethra.
- DMSA remains the gold standard for renal cortical imaging and provides relative renal function.

Management of Pediatric Urinary Tract Infection

Antibiotic Treatment

The goals of acute UTI management include eradicating the infectious agent, preventing renal scarring, and alleviating the child's symptoms. With successful antibiotic treatment, the urine usually becomes sterile after 24 hours (Beetz et al., 2002). **As may be expected, early antibiotic treatment of febrile UTI is a significant factor in limiting renal involvement and subsequent renal scarring** (Doganis et al., 2007; Hiraoka et al., 2003; Smellie et al., 1994; Winter et al., 1983). **One study of infants and young children with febrile UTI demonstrated that the incidence of acute scintigraphic renal lesions increased from 22% to 59% when the start of antibiotics went from 2 to 3 days from onset of symptoms** (Oh et al., 2012). **The rate of ultimate scar formation in this series also increased from 11% to 76.5% when the start of antibiotics went from 2 days to 6 days from the onset of symptoms, respectively.** The role of anti-inflammatory agents such as dexamethasone or methylprednisolone in reducing renal inflammation and ultimate scar formation has been demonstrated in several studies and is currently under investigation (Huang et al., 2011; Pohl et al., 1999; Sharifian et al., 2008).

Because a UTI frequently occurs in young children and neonates with nonspecific symptoms, and a definitive diagnosis based on urine culture may require a wait of 2 to 3 days, the clinician must maintain a high index of suspicion for UTI and must routinely begin antibiotics empirically. Surprisingly, although this empiric decision to begin antibiotics for a presumed UTI should be based on a UA and subsequently confirmed and adjusted based on urine culture results, a review of more than 40,000 outpatient pediatric UTIs suggests that a UA was obtained in only 75% of cases, and a urine culture was obtained only a little more than half the time (Copp et al., 2013). This practice may lead either to overtreatment with antibiotics in children who do not have UTIs or to undertreatment and therapeutic delay for those who do have UTIs but have a resistant bacteria requiring a different antibiotic. The indiscriminate use of broad-spectrum antibiotics also leads to increased side effects and bacterial resistance.

Inpatient Versus Outpatient Management

Management of suspected UTI should be based on a combination of factors including likely uropathogen, clinical status, and the reliability of the patient and the family to comply with medical recommendations. Fewer than 1% of patients evaluated for UTI in the outpatient setting require admission (Copp et al., 2011). Infants older than 2 months and nontoxic children with suspected pyelonephritis can be treated as outpatients as long as compliance with and tolerance to oral antibiotics is not an issue (American Academy of Pediatrics, 1999; Hoberman et al., 1999; Hodson et al., 2007; Montini et al., 2007). Most antibiotics result in extremely high urine antibiotic levels relative to serum, and several randomized comparative studies of oral and intravenous antibiotics have demonstrated no significant differences in the time elapsed to clinical improvement or to the prevention of renal scars (Bitsori and Galanakis, 2012; Hoberman et al., 1999; Hodson et al., 2007; Montini et al., 2007).

Hospitalization and parenteral antibiotics may be required based on patient age and clinical status. **A febrile UTI in newborns and young infants proceeds more frequently to urosepsis than it does in older children. Positive blood cultures are found in 20% of this age group, and this group is also more likely to develop electrolyte abnormalities including hyponatremia and hyperkalemia. For these reasons, newborns and young infants require hospitalization and parenteral antibiotics** (Beetz et al., 2002; Brady et al., 2010). Indications for hospitalization include infants younger than 1 month of age and, according to some, younger than 2 or even 6 months of age, toxic presentation or dehydration, intolerance to oral intake, and questionable compliance with antibiotics (Royal Children's Hospital Melbourne, 2011). Neonates require initial hospitalization and full septic evaluation along with parental antibiotics. After the diagnosis is confirmed by urine culture, the parenteral antibiotics may be changed to oral antibiotics depending on the clinical picture, which would include an improvement in symptoms. Significant clinical improvement, including defervescence, routinely takes at least 24 hours after beginning antibiotics (Hoberman et al., 1999). Within 48 hours of the start of therapy 90% of children have a normal body temperature, but if a child is not improving after 48 hours, an RBUS should be strongly considered. In addition, if urine culture results are not yet available, consideration should be given to broadening antimicrobial therapy (see Radiographic Imaging).

Antibiotic Duration

In children, antibiotic treatment lasting 7 to 14 days is recommended for febrile UTI because shorter courses have been proven inferior (American Academy of Pediatrics, 1999; Keren and Chan, 2002; Michael et al., 2003). With severe infections, such as focal pyelonephritis (previously termed acute lobar nephronia), a longer course of antibiotics of at least 3 weeks is sufficient in most cases (Beetz et al., 2002; Cheng et al., 2006). In many cases a renal abscess can also be treated with antibiotics; however, a lack of clinical response or resolution may require drainage. With less severe UTI, such as afebrile acute cystitis (lower UTI), a 2- to 4-day course has a reduced rate of recurrence compared with a single dose or a 1-day course and no significant difference compared with a 7- to 14-day course (Michael et al., 2003).

Antibiotic Selection

If a urine Gram stain was obtained, the results may help guide initial empiric antibiotic choice while awaiting urine culture results. *E. coli* remains the most common pediatric uropathogen (>80% of UTIs) (Edlin et al., 2013; Table 25.2). TMP-SMX and amoxicillin are used in approximately 50% of outpatient UTI visits, but these may be poor empirical choices because of high resistance rates of *E. coli*. Nitrofurantoin or a first-generation cephalosporin is an appropriate narrow-spectrum antibiotic choice for many children with a UTI; however, the age of the child and comorbid conditions should also be considered when selecting antibiotics (Copp et al., 2011; Edlin et al., 2013). Uropathogen prevalence and resistance rates also vary by gender and visit setting as well as by previous exposure to antibiotics, so these factors must be considered when choosing empiric antibiotic therapy. **Empirical treatment of acute UTI should be based on local/regional antibiograms that are revised and published on an annual basis because uropathogen prevalence and resistance patterns will vary regionally and will change with time** (Table 25.3). Table 25.3 lists common oral and parenteral antibiotics used for treatment of UTI along with common dosing and side effects.

TABLE 25.2

Uropathogen Prevalence by Gender and Clinical Setting[a]

ORGANISM	**MALE**		**FEMALE**	
	OUTPATIENT	**INPATIENT**	**OUTPATIENT**	**INPATIENT**
Escherichia coli	50% (48–52%)	37% (35–39%)	83% (83–84%)	64% (63–66%)
Enterobacter	5% (5–6%)	10% (8–11%)	1% (1–1%)	4% (4–5%)
Enterococcus	17% (16–18%)	27% (25–29%)	5% (5–5%)	13% (12–14%)
Klebsiella	10% (9–11%)	12% (10–13%)	4% (4–5%)	10% (9–11%)
Pseudomonas aeruginosa	7% (6–8%)	10% (8–11%)	2% (2–2%)	6% (5–7%)
Proteus mirabilis	11% (10–12%)	5% (4–6%)	4% (4–4%)	2% (2–3%)

[a] Based on national data from The Surveillance Network. Prevalence will vary based on region.

Data from Edlin RS, Shapiro DJ, Hersh AL, et al.: Antibiotic resistance patterns of outpatient pediatric urinary tract infections. *J Urol* 190(1):222–227, 2013.

TABLE 25.3

Details of Common Antibiotic Dosing

	DOSE	**COMMON SIDE EFFECTS**	**COMMENTS**
ORAL AGENTS			
Amoxicillin-clavulanate	20–40 mg/kg/day in 3 doses	Diarrhea, nausea/vomiting, rash	
TMP-SMX	6–12 mg/kg/day of TMP in 2 doses	Diarrhea, nausea/vomiting, photosensitivity, rash	Contraindicated <6 wk of age
Cefixime	8 mg/kg/day in 1 dose	Abdominal pain, diarrhea, flatulence, rash	
Cefpodoxime	10 mg/kg/day in 2 doses	Abdominal pain, diarrhea, nausea, rash	
Cefprozil	30 mg/kg/day in 2 doses	Abdominal pain, diarrhea, elevated LFTs, nausea	
Cephalexin	50–100 mg/kg/day in	Diarrhea, headache,	

	4 doses	nausea/vomiting, rash	
Nitrofurantoin	3–5 mg/kg in 2 doses	Nausea/vomiting, bad taste	Contraindicated <3 mo of age or when GFR is <50% or in children with G6PD deficiency
PARENTERAL AGENTS			
Ceftriaxone	75 mg/kg/day in 1 dose		Single daily dosing acceptable (Gauthier et al., 2004)
Cefotaxime	150 mg/kg/day divided q6-8h		
Ceftazidime	100–150 mg/kg/day divided q8h		
Gentamicin	7.5 mg/kg/day divided q8h		Single daily dosing acceptable alternative
Tobramycin	5 mg/kg/day divided q8h		
Piperacillin	300 mg/kg/day divided q6–8h		

G6PD, Glucose-6-phosphate dehydrogenase; *GFR,* glomerular filtration rate; *LFTs,* liver function tests; *TMP-SMX*, trimethoprim-sulfamethoxazole.

Data McCarthy PL, Sharpe MR, Spiesel SZ, et al.: Observation scales to identify serious illness in febrile children. *Pediatrics* 70:802–809, 1982.

In addition to *E. coli*, other common gram-negative bacterial uropathogens include *Klebsiella*, *Proteus*, *Enterobacter*, and *Citrobacter*. Gram-positive bacterial uropathogens include *Staphylococcus saprophyticus*, *Enterococcus*, and, rarely, *Staphylococcus aureus*. **Neonates and young infants should be covered for *Enterococcus* species when choosing empiric antibiotics because the incidence of infections with this uropathogen is higher in early infancy than at a later age** (Beetz and Westenfelder, 2011). ***Enterococcus* is frequently sensitive to ampicillin and first-generation cephalosporins.** A combination of ampicillin and a third-generation cephalosporin or aminoglycoside is considered a safe empiric choice for neonates and young infants receiving parenteral therapy. Aminoglycosides may be given in once-daily dosing and should be considered for patients at risk for *Pseudomonas* UTIs such as those with recent exposure to antibiotics or urinary tract abnormalities (Beetz and Westenfelder, 2011; Bitsori and Galanakis, 2012). Parenteral antibiotics may be converted to oral therapy in most children after several days based on culture results and the child's clinical response, including defervescence.

Most uropathogens are susceptible to narrow-spectrum antibiotic agents such as first-generation cephalosporins and nitrofurantoin. However, nitrofurantoin has poor tissue penetration and should not be used for febrile UTI/pyelonephritis. Nitrofurantoin has also been associated with increased risk of hemolytic anemia in infants less than 3 months of age and should not be used in this population. Similarly, TMP is contraindicated in premature infants and newborns less than 6 weeks of age (Beetz and Westenfelder, 2011). An empiric broad-spectrum antibiotic prescription is appropriate in children at risk for resistant UTI such as those with a history of previous UTI, recent antibiotic exposure, recent hospitalization, and presence of genitourinary anomaly (Allen et al., 1999; Cheng et al., 2008; Paschke et al., 2010). Broad-spectrum antibiotics include broad-spectrum penicillins (antipseudomonal penicillins and β-lactamase/β-lactam inhibitor combination penicillins), macrolides, fluoroquinolones, second-, third-, or fourth-generation cephalosporins, lincosamides, and carbapenems.

Although fluoroquinolones are highly effective against most uropathogens, bacterial resistance has increased as a result of widespread use. Fluoroquinolones should not be a first-line choice but should be reserved for those with suspected or proven resistant uropathogens such as *Pseudomonas aeruginosa*. In addition, the safety of quinolones in children has been questioned and is under investigation (Bradley et al., 2011).

Management After Urinary Tract Infection

After treatment of initial UTI, management is aimed at preventing subsequent UTIs. **Routinely repeating a urine culture in children treated with an antibiotic based on previous urine culture susceptibilities is not necessary** (Currie et al., 2003; Oreskovic and Sembrano, 2007). **Approximately 10% to 30% of children develop at least one recurrent UTI** (Nuutinen and Uhari, 2001; Peters et al., 2010; Shaikh et al., 2008; Winberg et al., 1975). **The recurrence rate is highest within the first 3 to 6 months after a UTI, and the more frequent and larger number of recurrent UTIs a child has had, the more likely he or she is to experience a subsequent UTI** (Kasanen et al., 1983; McCracken, 1984; Winberg et al., 1974). In boys younger than 1 year of age, 18% develop a recurrent infection, usually within the following year. If the initial infection is in a boy more than 1 year of age, his risk of a reinfection increases to 32%. A similar trend is noted in girls less than and greater than 1 year of age who have a recurrence risk of 26% and 40%, respectively (Winberg et al., 1974).

Parents should be counseled regarding the high risk of recurrent UTI and should be urged to seek prompt evaluation for subsequent febrile illnesses because prompt treatment from the time of onset of symptoms should help reduce renal damage. Renal scarring increases with an increasing number of febrile UTIs, with the risk going from 5% to 10%, 20%, 40%, and 60% after the first, second, third, fourth, and fifth pyelonephritic episodes, respectively (Jodal, 1987). Children who have had a febrile UTI should routinely have their height, weight, and blood pressure monitored by their primary care provider.

Identification of the risk factors predisposing a patient to UTIs helps direct individualized patient management by treating or eliminating these risk factors. UTIs, like infections in other sites of the body, are more likely to occur with increased inoculum and duration of exposure to the pathogen as well as in situations that compromise local and/or systemic immunity. Relative to UTIs, factors thought to increase the inoculum and duration of exposure include those that create urinary stasis as well as constipation. Surgical correction of obstructive uropathies should help reduce stasis. Infrequent voiding and urinary retention, or high pressures as may occur with dysfunctional voiding or obstructive uropathies, may compromise the local immunity of the bladder. As noted, a history of a recent UTI also predisposes the child to subsequent UTIs. In some patients, the risk factors responsible for recurrent UTIs may not be identifiable or modifiable, and these patients may benefit from nonspecific preventive therapies.

Prophylactic Antibiotics

The use of prophylactic antibiotics may be considered a nonspecific approach to the prevention of recurrent UTIs. The efficacy of prophylaxis has been questioned, even in children with VUR, by several relatively small randomized series including children with low grades of VUR (Garin et al., 2006; Montini et al., 2008; Pennesi et al., 2008; Roussey-Kesler et al., 2008). Neither the AAP guidelines nor the NICE guidelines recommend routinely prescribing prophylactic antibiotics to infants and children after their first UTI. **As may be expected, the benefit of prophylactic antibiotics is more easily demonstrated when used in specific populations known to be at high risk for recurrent UTI** (Brandström et al., 2010a). In populations known to be at higher risk for recurrent UTI, such as girls with dilating VUR (i.e., greater than or equal to grade III), prophylactic antibiotics have proven effective (Brandström et al., 2010a; Craig et al., 2009). **The following risk factors are associated with a low risk of recurrent UTI and therefore make it more difficult to demonstrate any benefit of prophylactic antibiotics: circumcised boys, no bowel or bladder dysfunction, no recent history of UTI, normal renal ultrasound or DMSA scan, a lack of anatomic abnormalities, and nondilating VUR** (Peters et al., 2010). The prospective randomized intervention for vesicoureteral reflux (RIVUR) trial compared TMP-SMX prophylaxis with placebo in 607 children with grade I-IV VUR after UTI; 554 of these patients were enrolled after their first UTI with a median age of 12 months. Importantly, the study also included children with bowel and bladder dysfunction (BBD), and of the 126 toilet-trained children, 56.3% had BBD. During the trial, 111 children had 171 recurrences of UTI, and 72.1% of these UTIs were febrile. The risk of febrile or symptomatic UTI recurrences was reduced by half in children receiving prophylaxis as compared with those receiving prophylaxis (25.5% vs. 37.4%; RR, 0.68; 95% CI 0.53–0.87), and this difference between the two treatment groups widened over time. However, further review of the data revealed that eight children would have to be treated with antibiotic prophylaxis for 2 years to prevent one case of febrile or symptomatic UTI. In addition, outcome renal scans (at the 2-year visit or 3–4 months after the child met treatment failure criteria) showed no significant difference between groups in the incidence of renal scarring (11.9% in the prophylaxis group and 10.2% in the placebo group; $P = 0.55$). The risk reduction for recurrent UTI was greatest in those children with bowel and bladder dysfunction at baseline, a history of febrile UTI, or higher grades of VUR (RIVUR Trial Investigators et al., 2014).

Antibiotic resistance is a concern regarding the use of prophylactic antibiotics. Multiple studies confirm that exposure to antibiotics increases the likelihood that any subsequent UTIs will be caused by bacteria resistant to the previously prescribed antibiotics (Allen et al., 1999; Brandström et al., 2010a; Conway et al., 2007; Craig et al., 2009; Paschke et al., 2010). This relates to the fact that the fecal flora frequently becomes resistant to the treatment antibiotic. In general, the risk of resistance appears to be about three times greater after treatment with antibiotics. Thus the prophylactic antibiotic chosen should be different than the therapeutic antibiotic used for the UTI.

The ideal antibiotic for prophylaxis would be effective against most uropathogens, be easily administered and tolerated without significant side effects, have high urinary concentrations and low serum concentrations, and make little impact on indigenous bacterial flora and bacterial resistance (Beetz and Westenfelder, 2011). The dosage is usually one-fourth the normal dose, and in toilet-trained children, it is routinely administered shortly before going to sleep in hopes of increasing the duration of antibiotic within the urinary bladder. Common choices for prophylactic antibiotics include TMP-SMX, TMP, nitrofurantoin, and first-generation cephalosporins. With increasing resistance of *E. coli* to TMP-SMX, its use in this manner is increasingly questionable. **Sulfonamides may compete for bilirubin binding sites on albumin and cause neonatal hyperbilirubinemia and kernicterus, so TMP-SMX is avoided during the first 6 weeks of life.**

Nitrofurantoin produces minimal effect on the fecal flora, and resistance rates have remained relatively low, making it an effective prophylactic antibiotic. Because serum levels with nitrofurantoin are low, it is not recommended for use with APN or urosepsis. In addition, it can cause hemolysis in children with glucose-6-phosphate dehydrogenase (G6PD) deficiencies by oxidizing hemoglobin to methemoglobin. This deficiency is found in about 10% of African-Americans, Sardinians, non-Ashkenazi Jews, Greeks, Eti Turks, and Thais. Long-term treatment has been associated with rare cases of pulmonary fibrosis.

Many unanswered questions exist regarding not only which patients benefit from prophylactic antibiotics but also the best therapeutic regimen. The ideal dosing and schedule, as well as the use of alternating antibiotics, remain to be defined. Patient noncompliance with a prescribed daily antibiotic is common (Daschner and Marget, 1975).

Cranberry juice has been suggested to reduce the incidence of UTIs. A meta-analysis that included adults and children demonstrated no UTI reduction for those using cranberry products as compared with placebo, water, or no treatment (Jebson and Craig, 2012). Several studies in children with neurogenic bladders also demonstrated no reduction on recurrent UTI (Foda et al., 1995; Schlager et al., 1999). However, several other studies in children did suggest a possible benefit of cranberry juice in reducing recurrent UTIs (Ferrara et al., 2009; Salo et al., 2012). At present, there does not appear to be enough evidence demonstrating conclusive benefit to warrant a recommendation for the routine use of cranberry juice or cranberry products in children for the prevention of UTIs.

Probiotics consist of live micro-organisms and have been reported to have possible beneficial effects in prevention of UTIs. A meta-analysis of 10 studies with 2865 children and adolescents showed that probiotics as monotherapy did not have a beneficial effect in reducing the incidence or recurrence of UTI. Moderate efficacy (RR = 0.92; 95% CI 0.85–0.99; $P = 0.02$) was demonstrated when a probiotic was used as adjuvant therapy to antibiotics (Hosseini et al., 2017).

Circumcision reduces the risk of UTIs in infants and toddlers (Wiswell et al., 1985). The risk reduction appears greatest in those with a history of recurrent UTIs and dilating VUR (Singh-Grewal et al., 2005). Some consider conditions that place boys at high risk for UTI as a relevant medical indication for circumcision. Such patients may have a history of recurrent febrile UTIs, obstructive uropathy, high-grade hydronephrosis, hydroureteronephrosis, or high-grade VUR (Zee et al., 2016). The benefit of prophylactic circumcision even in these patients is controversial.

Bladder and Bowel Dysfunction

Consideration and assessment of underlying bladder or bowel dysfunction as predisposing factors should occur with any pediatric UTI. **There exists a well-recognized association between bladder dysfunction and UTI, and bladder dysfunction predisposes children to recurrent UTI and renal injury**

(Hoebeke et al., 2001; Nijman, 2000). In particular, the risk of bladder colonization and UTI is increased in children with incomplete bladder emptying resulting from dysfunctional voiding or underactive bladder. In addition, there is an association between VUR and bladder dysfunction (Hoebeke et al., 2001; Koff et al., 1998; Schulman et al., 1999). It is thought that voiding against a closed sphincter can increase bladder pressure and may contribute to the development and to the persistence of VUR (Chandra and Maddix, 2000; Yeung et al., 1998, 2006). Treatment of bladder dysfunction, particularly overactive bladder, has been shown to improve the spontaneous VUR resolution rate, further suggesting an etiologic component for overactive bladder in the genesis of reflux (Homsy et al., 1985; Koff et al., 1998; Willemsen and Nijman, 2000).

Anorectal and lower urinary tract function are interrelated, and constipation is often associated with bladder dysfunction. Reported frequency of constipation associated with pediatric bladder dysfunction ranges from 30% to 88% (Burgers et al., 2013a, 2013b; O'Regan et al., 1986; Schulman et al., 1999). This relationship between abnormal bowel and bladder function is referred to as BBD or as the dysfunctional elimination syndrome (DES) (Bower et al., 2005; Burgers et al., 2013b; Feng and Churchill, 2001; Koff et al., 1998). **Children with VUR and bowel and/or bladder dysfunction are at particularly high risk for developing recurrent pyelonephritis** (Hellerstein and Nickell, 2002; Leslie et al., 2010; Sillen et al., 2010; Thompson et al., 2001)**. Recurrent UTI is estimated to occur in about 45% of these children as opposed to 15% without BBD** (Peters et al., 2010). **Treatment of constipation has been shown to reduce recurrent UTIs significantly and to improve bladder function** (Erickson et al., 2003; Loening-Baucke, 1997).

Detailed information regarding treatment of pediatric bladder and bowel dysfunction is reviewed in Chapters 30 and 36. In general, the initial conservative therapeutic measures for treating the child with bladder dysfunction include voiding behavior modification with timed voiding schedules and treatment of constipation, if present (Allen et al., 2007; Erickson et al., 2003). In patients who fail conservative treatment, directed therapy is focused toward improving the specific cause of bladder dysfunction. Targeted interventions may include pharmacologic therapy, biofeedback, electrical stimulation therapy, surgery, clean intermittent catheterization, or a combination of these therapies (Malm-Buatsi et al., 2007; Nelson et al., 2004; Van Arendonk et al., 2006a, 2006b). For children with a neurogenic bladder on intermittent catheterization, increasing the frequency of catheterization has been associated with decreased rates of recurrent UTI.

Management of Vesicoureteral Reflux

VUR remains a risk factor for recurrent pyelonephritis and renal scarring. The risk of both of these events increases with increasing grades of VUR and seems to become significant in most series with dilating VUR (i.e., grade III or higher) (Brandström et al., 2010a, 2010b; Conway et al., 2007; Hellerstein and Nickell, 2002; Holmdahl et al., 2010; Leslie et al., 2010; Montini et al., 2008; Oh et al., 2012; Roussey-Kesler et al., 2008; Shaikh et al., 2010). As previously noted, multiple studies have challenged the dogma that all children with a febrile UTI and reflux benefit from the diagnosis of VUR and subsequent treatment of this condition by either continuous antibiotic prophylaxis or surgical correction (Cooper et al., 2000; Garin et al., 2006; Hellerstein and Nickell, 2002; Leslie et al., 2010; Montini et al., 2008; Pennesi et al., 2008; Reddy et al., 1997; Roussey-Kesler et al., 2008; Subcommittee on Urinary Tract Infection et al., 2011; Thompson et al., 2001). Almost paradoxically, as more studies provide additional information regarding VUR, determining the ideal management of a patient with VUR has become increasingly complex and is discussed in detail in Chapter 29.

Sequelae of Pediatric Urinary Tract Infections

Renal Scarring

Pyelonephritic scarring occurs most commonly in the poles of the kidney and is associated with compound papillae (Hannerz et al., 1987). Children with pyelonephritis and VUR are at increased risk for renal scar development, and this risk increases with increasing grade of VUR (Lee et al., 2012; Oh et al., 2010; Shaikh et al., 2010). **After the acute inflammatory phase, the ultimate scar involves a loss of tissue that is reflected on radiographic imaging as thinning of the renal parenchyma over the calyces. The calyces themselves may become blunted and deformed.** It can be difficult or impossible to distinguish scar from regions of congenital dysplasia by radiographic imaging, although patients with a small kidney and diffusely decreased isotope uptake and decreased differential renal function are often considered to have renal dysplasia. Prompt antimicrobial treatment decreases the chance of permanent renal damage, as does the elimination of any subsequent episode of pyelonephritis (Oh et al., 2012). One review noted that for every hour antimicrobial therapy was delayed in treating a febrile UTI, the odds of new renal scarring increased by 0.8% (Shaikh et al., 2016). Others have shown that the odds of developing a renal scar double if antibiotics are begun after 72 hours from the start of a febrile UTI compared to children begun on antibiotics within 48 hours (Karavanaki, 2017). The use of anti-inflammatory agents to minimize renal injury and scar during the acute phase of pyelonephritis is under investigation (Huang et al., 2011; Pohl et al., 1999; Sharifian et al., 2008).

Xanthogranulomatous Pyelonephritis

Xanthogranulomatous pyelonephritis (XGP) is a specific form of chronic inflammatory kidney disease rarely seen in children that is usually associated with an element of obstruction and, most commonly, *Proteus* or *E. coli* (Rippentrop et al., 2002). Symptoms are often vague and nonspecific and may include fever, abdominal or flank pain or mass, and more nonspecific symptoms including weight loss and failure to thrive. Laboratory studies may demonstrate leukocytosis, anemia, and pyuria.

Imaging may demonstrate a masslike lesion with focal or diffuse renal involvement as well as perinephric extension (Cooper and Turner, 1997; Eastham et al., 1994; Malek and Elder, 1978). This may be mistaken for a malignancy and requires a high index of suspicion (Inouye et al., 2013; Nam et al., 2012). CT images may demonstrate areas of low attenuation that do not enhance as well as dilated calyces. Renal calculi are present in 38% to 70% of patients (Anhalt et al., 1971; Malek and Elder, 1978).

Nephrectomy is the treatment of choice for the diffuse form, whereas partial nephrectomy or conservative medical therapy may be indicated to manage focal XGP (Cooper and Turner, 1997; Nam et al., 2012). Technically, these operative cases can be extremely difficult because the process may extend beyond the kidney, distorting and destroying normal anatomy as it involves and encases surrounding structures, including the psoas muscle and, at times, even the great vessels (Loffroy et al., 2007; Malek and Elder, 1978).

Long-Term Sequelae

It is difficult to predict which children will develop long-term sequelae of pediatric UTI, including hypertension, preeclampsia, or chronic kidney disease (CKD) because of a lack of clear data establishing the long-term consequences after pediatric UTIs. A review of 23 papers including a total of 3573 children demonstrates that the majority of children with a history of febrile UTI develop no long-term sequelae (Toffolo et al., 2012). This seems to be true in particular if at birth the children had normal kidneys that were unaffected by significant renal dysplasia. **Toffolo et al. estimated that only 0.4% of children with normal renal function at the start of follow-up experienced a decrease in renal function.** This rate is consistent with that found in the prospective International Reflux Study in Children (Smellie et al., 1998) and in another series of 226 adults with a history of childhood UTI who were followed for 10 to 41 years, which noted that only two patients developed CKD that was attributed to UTIs (Jodal et al., 2006). Wennerstrom et al. (2000) demonstrated a decrease in mean GFR after 16 to 26 years of follow-up more frequently in children with bilateral renal scars but not unilateral scars compared with children without scars. This same group showed no significant difference in mean 24-hour ambulatory blood pressure between those with and without urographic renal scars. Two other studies with follow-up of 22 and 41 years demonstrated an increased prevalence of hypertension of 29% and 35%, respectively, in patients with scars, suggesting that scars are a risk factor for the development of hypertension (Bailey et al., 1992; Jacobson et al., 1989). The risk of hypertension appears to increase with the severity of renal scarring. It has also been demonstrated that during first pregnancies, hypertension was significantly more common in women with severe renal scarring (Martinell et al., 1996; Smellie et al., 1998).

Children with significant bilateral renal scars or reduction of renal function warrant long-term follow-up for assessment of hypertension, renal function, and proteinuria. Studies suggest that proteinuria may not only be a clinical feature of CKD but may hasten its progression. The use of renin-angiotensin antagonists may slow the progression of CKD in some of these patients (Wong et al., 2009). A historical cohort study demonstrated that with long-term follow-up 140 of 18,592 (0.75%) patients with a history of congenital anomalies of the kidney or urinary tract, pyelonephritis, or glomerular disease and no proteinuria or elevated creatinine during adolescence subsequently developed end stage renal disease (HR = 4.19, 95% CI 3.52–4.99 [Calderon-Margalit et al., 2018]).

Key Points: Management and Sequelae

- Delay in antibiotic treatment of a febrile UTI increases the incidence of renal parenchymal involvement and ultimate scar formation.
- Newborns and young infants should be hospitalized because of a higher incidence of urosepsis than older children.
- A total of 7 to 14 days of antibiotic treatment is recommended for children with febrile UTI; a 2- to 4-day course is acceptable for afebrile cystitis.
- Empiric antibiotic selection should be guided by local/regional antibiograms because of changing uropathogen prevalence and resistance patterns.
- Nitrofurantoin should not be used for febrile UTI/pyelonephritis.
- A total of 10% to 30% of children develop at least one recurrent UTI.
- Antibiotic prophylaxis has been demonstrated to decrease subsequent UTI in high-risk populations such as girls with dilating reflux.
- Bowel and bladder dysfunction increase the risk of recurrent UTI and should be evaluated and treated in any child with a UTI.

- Although the risk of long-term sequelae of pediatric UTIs is relatively low, children with significant bilateral renal scars or a reduction of renal function warrant long-term follow-up for the assessment of hypertension, renal function, and proteinuria.

Uncommon Pediatric Urinary Tract Infections

Viral Cystitis

Acute hemorrhagic cystitis in children has occasionally been related to UTIs caused by adenovirus-11. In a series from Mufson et al. (1973) that evaluated children suffering from hemorrhagic cystitis, adenovirus-11 was recovered from the urine in 14.5% of patients, adenovirus-21 was found in the urine of 9% of these children, and *E. coli* was present in 17.4% of the cohort. In the vast majority of the individuals, no infectious cause was identified.

Viral cystitis has commonly been identified in individuals after bone marrow transplantation and in other immunosuppressed individuals. Without successful treatment, severe viral cystitis and associated hemorrhagic cystitis is associated with a 50% to 80% mortality rate in these children (Gavin and Katz, 2002). BK virus, a DNA virus of the polyomavirus genus, has also been found in the urine of immunosuppressed and especially bone marrow transplant patients, causing symptomatic and asymptomatic infections (Apperley et al., 1987; Bedi et al., 1995).

Funguria

Fungal UTIs appear to be increasing in prevalence and are commonly associated with individuals who have recently received antibiotics or who have had indwelling urethral catheters. In one neonatal intensive care unit, funguria increased 10-fold throughout a 10-year period (Kossoff et al., 1998). Predisposing factors in children include antibiotic use, prematurity, intravenous and umbilical artery catheterization, parental nutrition, and an immunocompromised state (Keller et al., 1977). The urinary tract may serve as a portal of entry and as a site of disseminated fungal infection. In children with disseminated candidiasis, the kidney is the most commonly involved organ (Keller et al., 1977). *Candida* species are the most common cause of fungal UTI; C*andida albicans* is the most common species involved in these infections, followed by *Torulopsis glabrata*. It is important to recognize the infections caused by *Torulopsis glabrata* because these are commonly resistant to fluconazole (Kauffman et al., 2000).

Fungal bezoars may also form in the renal pelvis and potentially create urinary obstruction in these children (Bartone et al., 1988; Keller et al., 1977). For this reason, renal ultrasound may be beneficial in evaluating these patients, especially if the funguria is persistent. Urinary alkalization and oral antifungal therapy may occasionally dissolve some fungal balls, but if the child is suffering from renal obstruction, percutaneous or surgical removal of these fungus balls is necessary. Percutaneous drainage may also be needed so that local antifungal therapy can be administered. In these individuals, local and systemic amphotericin B and/or oral fluconazole may be useful for treatment. If the fungal balls are shown to persist, endoscopic or open surgical removal may be necessary.

The timing of treatment of asymptomatic funguria that are related to indwelling urethral catheters continues to be debated. In individuals with funguria secondary to these foreign bodies, progression to disseminated candidemia is rare (Kauffman et al., 2000). When repeated urine cultures grow greater than 10,000 to 15,000 CFU/mL, antifungal treatment is generally recommended. Stopping antibiotic therapy, changing or removing urethral catheters, and urinary alkalinization may be helpful in some cases, but these do not always clear the fungus from the urine. Prospective studies with intravesical amphotericin B bladder irrigation and oral fluconazole show that both may clear the funguria (Gubbins et al., 1994, 1999). Fluconazole has been used successfully in children, although its use is contraindicated in children less than 6 months of age.

Core Principles of Perioperative Management in Children

Sherry S. Ross MD, Janey R. Phelps MD

Pediatric Anesthesia

Perioperative Home

Over 20 years ago, the American Academy of Pediatrics defined the Patient/Family-Centered Medical Home in policy statements describing it as care that is accessible, patient- and family-centered, continuous, comprehensive, and culturally sensitive. This resulted in the development of the Perioperative Surgical Home (PSH) defined by the American Society of Anesthesiologists (ASA) as an innovative, patient-centered surgical continuity of care model that incorporates shared decision making with the goal to create methods for improving the patient/family perioperative experience while improving clinical outcomes and controlling costs. This concept was greatly influenced by the Patient Protection and Affordable Care Act (PPACA) of 2010 in its introduction of accountable care organizations (ACOs; Patient Protection and Affordable Care Act, 2010). ACOs are designed to hold multiple providers jointly accountable for achieving quality targets and reductions in cost (Kash et al., 2014, Vetter et al., 2013).

The perioperative experience is subdivided into groups that include preoperative, intraoperative, postoperative, and postdischarge. Multidisciplinary representatives work together in each group to create a set of standardized care pathways founded on evidence-based medicine. This includes development of Early Recovery After Surgery (ERAS) pathways to promote early mobilization after surgery; increase the use of multimodal analgesia and decrease opioid consumption; endorse early removal of surgical drains; encourage early advancement of diet; and decrease the length of hospital stay. The development of Pediatric PSHs, with a multidisciplinary approach led by both surgeons and anesthesiologists, with defined evidence-based guidelines and protocols will result in appropriate resource utilization and increase patient and provider satisfaction.

Anesthesia and Potential Neurocognitive Effects

On December 14, 2016, the United States Food and Drug Administration (FDA) made a safety statement regarding the possible neurocognitive effects of exposure to anesthesia in children and pregnant women. **The statement warns**

that repeated or lengthy use of general anesthetic and sedation drugs during surgeries or procedures in children younger than 3 years of age or in pregnant women during their third trimester may affect the development of children's brain (FDA Statement, 2016). This warning comes after a plethora of animal studies demonstrated neuropoptosis and cognitive deficits in animals after exposure to anesthesia (Rappaport et al., 2015). These studies extrapolate the period of neuronal vulnerability comparative with the fetal brain in the third trimester, newborns, and children up to 3 years of age. The FDA acknowledges that a number of surgeries in this age group cannot be delayed but stress that the risk and benefits of nonemergent surgeries should be carefully weighed, especially if the surgery will be longer than 3 hours or if multiple surgeries are required (FDA statement, 2016).

Although the FDA has released a safety statement, studies are still lacking that provide direct translation of the animal studies to humans. The FDA has partnered with the International Anesthesia Research Society to create Smart TOTs with the goal to design, implement, and conduct long-term studies in humans to answer this question. The General Anesthesia Compared to Spinal Anesthesia (GAS) study, sponsored by Smart TOTs, is an ongoing international, multicenter, randomized controlled trial comparing neurocognitive outcomes following randomization to either awake-regional anesthesia or to sevoflurane-based general anesthesia in children younger than 60 weeks of age but born at more than 26 weeks' gestation who require inguinal hernia repair. The initial 2-year follow-up results were published in January 2016, and authors reported no difference in cognitive development scores between the two study arms (Davidson et al., 2016). The Pediatric Anesthesia NeuroDevelopment Assessment (PANDA) project is another study sponsored by Smart TOTs and is a sibling-matched observational cohort study that examined whether a single anesthesia exposure in healthy children younger than 3 years of age is associated with an increased risk for impaired global cognitive function (IQ) as the primary outcome and abnormal domain-specific neurocognitive functions and behavior as secondary outcomes at 8 to 15 years of age. The study found that mean IQ scores were not significantly different between the exposed and unexposed siblings, with both groups scoring somewhat higher than average. This study was not able to evaluate the effects of prolonged or repeated exposures to anesthetics (Sun et al., 2016). Other studies have shown different outcomes including a study comparing 33,514 children exposed to anesthesia with 159,619 that were not exposed. The authors reported that anesthetic exposure before 4 years of age was associated with slightly lower school grades and IQ test scores (Glatz et al., 2017).

Research is ongoing in an attempt to determine the long-term effects of anesthesia and sedation on the developing brain of infants and children. In the meantime, the pediatric urologist must stay abreast on this topic. Many children's hospitals have crafted an institutional statement for families to address the FDA's statement and keep their patients informed. **In situations in which a surgery is not elective, it is important to acknowledge and discuss each parental concern with what is known, including the fact that initial human studies conclude a short exposure to a single anesthetic does not lead to decreased neurocognitive dysfunction and that patients deserve a high-quality anesthetic and appropriate pain control and the lack of such can lead to increased morbidity** (Soriano and Anand, 2005).

Key Points

- Families should be informed of current FDA recommendations including what is known and what studies are currently underway to allow thorough informed consent.

Preoperative Assessment and Preparation for Surgery

Anesthesia Risk

The administration of anesthesia is not without risk, and certain patient conditions, such as upper respiratory infections, asthma exacerbations, dehydration, uncontrolled diabetes, prematurity, and febrile illnesses, increase the risk for a complication. Comorbidities can also increase the risk associated with anesthesia administration. Strict adherence to the American Society of Anesthesiology nil per os (NPO) guidelines decreases the risk for potential aspiration. Additional risks include postoperative nausea and vomiting, bronchospasm, laryngospasm, stridor, emergence delirium, and postanesthesia maladaptive behaviors. Rare but more severe risks include allergic reactions to anesthetic medications, anaphylaxis, aspiration, malignant hyperthermia, and death. Although discussion of these risks is typically covered with the family by the anesthesia team, the pediatric urologist should be well versed in this area.

Preoperative Setting

Preoperative preparation is the foundation of ensuring a safe procedure, favorable outcomes, and satisfied families. Numerous studies have shown that pain is influenced by expectations about treatments and pain stimuli intensity (Atlas and Wager, 2012). It is important to ensure that children and parents have realistic postprocedure pain expectation that is delivered in an understandable and age-based language for a more positive emotional and physical outcome (Jaaniste et al., 2007; Jipson and Melamed, 2007; Noel et al., 2012). Certified child life specialists (CCLSs) are trained professionals who are experts in assisting children and families through various techniques to help overcome anxiety-filled experiences in the health care setting. When possible, a CCLS should be utilized in the preoperative setting to help with education and expectations and reduce both child and parental anxiety (Brewer et al., 2006; Grissom et al., 2016; Klosky et al., 2004). Information technology devices (personal computers, smartphones, handheld video games) are usually easily accessible, are cost-effective, can be used at any time or place in the preoperative or perioperative period, and have been shown to reduce distress in children (Faber et al., 2013; Manning et al., 2013; Muessig et al., 2013; Schoffman et al., 2013). Recent studies have found that use of virtual reality–guided operating room tours significantly reduces anxiety and improves compliance during the induction of anesthesia in children compared with conventional information (Ryu et al., 2017). Preoperative anxiety and behavioral stress is an important issue in pediatric surgery patients and may affect up to 50% of children who undergo surgical procedures (Kain et al., 1996). **Additionally, preoperative anxiety in children is predictive of postoperative pain levels and behaviors.** Studies have reported that children with high levels of preoperative anxiety have higher pain scores after surgery with a slower pain recovery after discharge. Higher anxiety is also predictive of emergence delirium, defined as agitation, crying, and/or thrashing during the recovery period (Kain et al., 2006). **New-onset maladaptive behaviors such as general anxiety, nighttime crying, enuresis, separation anxiety, and temper tantrums may occur in up to 50% of children who have undergone surgery, and although these behaviors appear to improve over time, some may persist past the postoperative period** (Kain et al., 1996, 2004). This highlights the importance of targeting ways to decrease both child and parental anxiety (Kain et al., 2004).

Special Preoperative Considerations

Jehovah's Witness

Jehovah's Witness is an evangelical religion with the belief that an individual's life is contained within blood and that accepting transfusion of blood and blood products is sinful. **Parents who are responsible for a child may want to refuse blood products on behalf of their children. However, the surgeon's legal and ethical obligation is with the child patient and not the parents.** The American Academy of Pediatrics recommends that health care providers recognize and respect the importance of religion and avoid unnecessary polarization when conflict over religious practices occur (American Academy of Pediatrics, 1997). However, it should be clear that surgeons and anesthesiologists will not allow a child to die for lack of blood products (Kiran et al., 2014). At our institution, parents are required to sign a separate consent explaining that medical personnel will override their refusal of blood products in life-threatening instances. If this occurs, an automatic court order is submitted to override parental refusal. **Pediatric urologists should be aware of laws in their state and policies at**

their institution.

Department of Social Services

Children in the custody of the Department of Social Services may undergo surgery and anesthesia with consent from a court-ordered legal guardian or designee. In these situations, it is important to either obtain surgical and anesthetic consents preoperatively or ensure that the designee is present or available for consent.

Pain Assessment Tools

The International Association for the Study of Pain defines pain as an unpleasant sensory and emotional experience associated with actual or potential tissue damage (Merskey and Bogduk, 1994). This definition illustrates the complexity of pain, which is magnified in pediatric patients when the ability to assess pain is limited because of cognitive ability and restricted communication skills. Self-assessment of pain is considered the gold standard, but the ability to use self-assessment measurements to rate pain is not present in children younger than 3 years of age.

The age-based self-assessment pain tools that have been validated in children are listed in Fig. 26.1 (von Baeyer, 2006). Commonly used pain scales in children are the Wong-Baker FACES pain rating scale and the numeric pain rating scale (Fig. 26.2). Objective pain scales are available for premature infants (e.g., the PIPP [Premature Infant Pain Profile]), neonates (e.g., the NIPS [Neonatal Infant Pain Scale], CRIES [assess crying, oxygenation, vital signs, facial expression and sleeplessness]) and nonverbal and cognitively impaired children (e.g., FLACC [Face, Legs, Activity, Cry, Consolability], CHEOPS [Children's Hospital of Eastern Ontario Pain Scale]). While the FLACC is a commonly used objective pain scale for nonverbal and cognitively impaired children, its interpretation in the immediate postoperative period can be confusing in the presence of emergency delirium (Manworren and Hynan, 2003; Merkel et al., 1997; Voepel-Lewis et al., 2002).

Pain should not only be described in terms of intensity, but it is just as important to qualify the pain in terms of location and duration and to ask what makes it better or worse. The quality of the pain should be understood. Pain cannot be appropriately treated until the location of it is determined. Interestingly, pain is not always at the surgical site.

NPO Status

Fasting Times

Preoperative fasting times have been well established by the ASA (ASA, 2011), the Canadian Anesthesiologists' Society (Merchant et al., 2013), and the European Society of Anaesthesiology (Smith et al., 2011) for both adults and children. See Table 26.1 for the ASA NPO guidelines (Flick and Schears, 2002; Schmitz et al., 2011). Carbohydrate drinks may reduce thirst and hunger and assist with decreasing irritability in young children so should be allowed (Oyama et al., 2011; Hausel et al., 2001). **Prolonged fasting can lead to a variety of adverse effects such as hunger, thirst, hypoglycemia, and dehydration (Hung, 1992; Experts debate NPO, 1994).** Dehydration is especially important for the preoperative child because their potential for fluid loss is higher than for adults (Manworren, 2000). In light of the negative effects of prolonged dehydration and studies demonstrating that clear liquids are cleared faster than previously thought, some European pediatric societies have published a consensus statement endorsing clear liquids up to 1 hour before anesthesia. The consensus statement has been endorsed by the Association of Paediatric Anaesthetists of Great Britain and Ireland, the European Society for Paediatric Anaesthesiology, and L'Association Des Anesthesistes-Reanimateurs Pediatriques d'Expression Francaise (Thomas et al., 2018). In the inpatient setting, maintenance intravenous fluids during the preoperative fasting period may prevent dehydration (Ferrari et al., 1999). In the outpatient setting, when NPO guidelines are followed, fasting fluid deficit is typically minimal, but fasting recommendations are not always followed, so fluid deficits may be high. Effort should be made to schedule surgical cases appropriately and to proceed with younger children earlier in the day because they are more vulnerable to hypovolemia.

TABLE 26.1

American Society of Anesthesiologists NPO Guidelines

INGESTED MATERIAL	MINIMUM FASTING PERIOD (hours)

Clear liquids	2
Breast milk	4
Infant formula	6
Nonhuman milk	6
Light meal	6
Regular meal	8

In emergency situations, the need for surgery should be weighed against the risk for pulmonary aspiration if NPO status is unknown or if guidelines are not met.

Modified from Apfelbaum JL, Agarkar M, Connis RT; American Society of Anesthesiologists Committee. American Society of Anesthesiologists: Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective procedures: an updated report by the American Society of Anesthesiologists Committee on Standards and Practice Parameters. *Anesthesiology.* 2011;114(3):495–511.

In emergency and urgent surgical cases in which delaying surgery can be detrimental to the patient, gastric content aspiration can result in subsequent development of pneumonitis (James et al., 1984; Raidoo et al., 1990). Rapid-sequence induction and intubation was introduced into anesthesia practice to protect the lungs from aspiration of gastric contents in patients with a full stomach (Neuhaus et al., 2013).

Special NPO Situations

Ketogenic Diet

Patients with epilepsy may be on a ketogenic diet, and it is generally recommended that they remain on their diet preoperatively with the same NPO instructions of a light meal 6 hours preinduction and clears 2 hours preinduction. **They should receive carbohydrate-clear fluids and avoid of drugs that can increase gluconeogenesis, such as dexamethasone** (Soysal et al., 2016; Sampath et al., 2007).

Enteral Tube Feeds

Enteral formulas should be discontinued 6 hours before induction of anesthesia, however pedialyte can be given up to 2 hours before induction (Nespoli et al., 2012). For patients with postpyloric feeding tubes, there is a decreased risk for gastroesophageal reflux and pneumonia, and some may advocate that feeds can continue for nonabdominal surgeries (Jiyong et al., 2013). However, at our institution the same NPO guidelines are used regardless of postpyloric feeds because exact positioning of the tube is not always known and the morbidity associated with aspiration can be high.

Diabetes and Metabolic Disorders

Patients with diabetes and other metabolic disorders deserve special considerations because volume depletion caused by preoperative fasting, coupled with discontinuation of outpatient diabetes medications may contribute to preoperative hyperglycemia (Hans et al., 2006). If possible, elective surgery for children with diabetes should be delayed until glycemic control is optimized. Recommendations include absence of ketonuria, normalized serum electrolytes, and HbA1c value near or within the recommended age-appropriate range (Rhodes et al., 2005). Although preoperative admission is not necessary, some studies have recommend admission for major surgical procedures to optimize metabolic control (Chadwick and Wilkinson, 2004). The patient should never undergo anesthesia without a blood glucose determination before the anesthetic is started. If the surgery has to be delayed for any reason, frequent blood glucose monitoring is mandatory. **It should be the goal that all diabetic patients are scheduled as first-case starts.**

Metformin should be discontinued 24 hours before the procedure because of a long half-life and the risk for lactic acidosis in the presence of dehydration, hypoxemia, or poor tissue perfusion (Mercker et al., 1997). Other oral drugs, such as sulfonylureas and thiazolidinediones, may be discontinued on the morning of the procedure. Insulin-dependent patients should receive their normal dosages of insulin on the day before surgery (Rhodes et al., 2005). At our institution, we recommend that one-half the amount of any long-acting insulin should be given the night before surgery.

The planned surgical procedure directs management of the diabetic child treated with an insulin pump. Specific recommendations should be discussed with the anesthesiologist and/or endocrinologist. In brief, for short minor procedures the patient should continue the insulin pump. For longer procedures, some protocols recommend intravenous insulin infusions or subcutaneous insulin glargine (Glister and Vigersky, 2003). Pediatric diabetic patients who require emergency surgery are typically managed with intravenous insulin infusion and frequent blood sugar checks (Rhodes et al., 2005).

A preoperative anesthesia consult should be considered in patients with metabolic and mitochondrial disorders. Patients with mitochondrial disorders can have an exacerbation of their disease with administration of propofol and lactated Ringer's solution, so these are traditionally avoided. There are numerous metabolic disorders, and it is beyond the scope of this chapter to address each one. However, in general, metabolic disorders such as glycogen storage disorder and urea cycle disorders result in impaired glucose metabolism. These patients cannot tolerate periods without a glucose source and therefore must have glucose-containing fluids while NPO. For these patients, preoperative discussions with the pediatric anesthesiologist are important, and preoperative hospitalization for glucose management should be considered.

Medication Administration

Fasting patients can take medications with a clear fluid 2 hours or more before surgery. **Medications that should be taken on the morning of surgery include antiseizure, gastrointestinal reflux, and asthma medications**. Medications that should not be taken include warfarin and aspirin (stop 7 to 10 days preoperatively), herbal medications, and angiotensin-converting enzyme inhibitors. Some herbal therapies such as Valeria and medications with rebound effects when stopped suddenly (e.g., Clonidine) should not be stopped without physician supervision (Lerman, 2013).

Preoperative Studies

Laboratory Tests

Although some institutions may order routine preoperative studies or laboratory tests, the use of routine preoperative blood testing has been thoroughly evaluated in the literature, and most studies report that in the absence of a clinical indication, routine laboratory evaluation has little use and is not cost-effective (Delahunt and Turnbull, 1980; Johnson and Mortimer, 2002; Kaplan, 1988; MacPherson et al., 2005). Preoperative laboratory tests should be obtained in a thoughtful manor and reserved for patients undergoing complex procedures with the potential for hemodynamic shifts and significant blood loss. Premature infants, patients with metabolic disorders, or patients with complex medical conditions may require preoperative laboratory tests. **The ASA recommends that pregnancy testing should be offered to female patients of childbearing age and to those in whom the result would alter the patient's management** (Apfelbaum et al., 2012). Our institutional policy is that girls of menstrual age receive a urin human chorionic gonadotropin (Hcg) test preoperatively.

Chest X-Ray and Electrocardiogram

Routine preoperative chest x-rays and electrocardiograms (ECGs) are not indicated in pediatric patients, and both tests should be reserved for patients with an indication for the study. It should be noted that a murmur alone is not an indication for an ECG, however pathologic murmurs or patients with cardiac symptoms should be evaluated by cardiology (Lerman, 2013). Last, the need for bacterial endocarditis prophylaxis should be clearly understood and appropriate antibiotic prophylaxis administered in the preoperative period (Nishimura et al., 2017; Wilson et al., 2008).

Pulmonary Function Testing

Pulmonary function test in certain patients, such as patients with poorly controlled asthma and severe scoliosis, may be indicated and the results can help with postoperative planning (Lao et al., 2013).

Urine Evaluation

Urologic procedures in which the urinary tract is opened electively, such as bladder reconstruction, or in cases of diagnostic or therapeutic endoscopy, there is an increased risk for postoperative infection (Cruse, 1992). In these cases, preoperative urine culture is important to identify urinary pathogens and select bacteria-sensitive antibiotics. **Positive urine cultures should be treated before surgical intervention** (Cai et al., 2016). Asymptomatic bacteriuria can be clinically significant and should be treated preoperatively in patients if a sterile urine sample can be obtained (Raz, 2003).

Comorbidities: Perioperative Planning and Postoperative Considerations

Premature Infants

Infants born before 37 weeks’ gestation are considered premature, and those born before 26 weeks or weighing less than 800 g are considered micro-preemies. **The risk associated with anesthesia is greater in preterm neonates because of their immature organ systems.** Respiratory function in the premature infant is challenging because of inadequate surfactant levels, especially in infants born before 34 weeks' gestation. Premature infants may also have higher oxygen consumption and low pulmonary functional residual capacity, as well as tracheomalacia (McCann and Soriano, 2014). **Premature infants have a high risk for postoperative apnea during the first 12 to 23 hours postanesthesia, which can result in death.** Therefore, 23-hour postoperative observation with cardiorespiratory monitoring is recommended in premature infants less than 50 to 60 weeks’ postgestational age (Cote et al., 1995; Davidson et al., 2015; McGregor et al., 2002). **Term infants also have an increased risk for postoperative apnea and should be observed for 23 hours if less than 44 weeks’ postgestational age.**

Premature infants, especially those born less than 28 weeks' gestational age, are at risk for retinopathy of prematurity and blindness, which can be exacerbated by hyperoxia, so the goal is to tolerate oxygen saturation in the low 90s (McGregor et al., 2002). Premature infants are at increase risk for hypothermia because they have immature skin, decreased brown fat, and a larger surface–to–body area ratio. Therefore a warm environment is mandatory (McCann and Soriano, 2014). Also, there is a higher potential for large fluid losses because of higher rates of evaporation from skin and surgical wound sights as well as decreased ability to concentrate urine (McCann and Soriano, 2014).

Asthma and Pulmonary Disease

Asthma control should be optimized before any elective procedure to decrease the risk for morbidity and mortality. Asthmatics and patients with any pulmonary pathology are at increase risk for intraoperative bronchospasm and laryngospasm (Gal, 1994). **The most dangerous times for an airway event is during induction and emergence from anesthesia because of mechanical stimulation, and vigilance is required for early recognition and treatment** (Olsson 1987; Bordet et al., 2002). **It is important not to examine or stimulate the patient at these times.**

For children with asthma, continuation of inhaled beta-2-agonist has been shown to improve lung function and decrease perioperative respiratory adverse events (Scalfaro et al., 2001; Silvanus et al., 2004). Perioperative corticosteroids are reportedly safe, but oral steroids should be utilized only in children with more severe lung disease to avoid the risk for postoperative wound infection and interference with surgical site healing (Kabalin et al., 1995; Vathenen et al., 1991).

Acute Upper Respiratory Tract Infection (URTI)

URTI increases the risk for adverse events, and a risk-benefit analysis should occur for all elective cases in the face of a URTI. Ideally, surgery should be delayed for 2 to 8 weeks, depending on severity, to allow resolution of inflammation and decrease the risk for perioperative respiratory adverse events (Von Ungern-Sternberg et al., 2010).

Cardiovascular Anomalies

Congenital heart disease is the most common form of congenital abnormality occurring in 1% of newborns (Marelli et al., 2007). **Children with a history of congenital heart disease have a higher reported rate of perioperative cardiac arrest with an increased risk for perioperative morbidity and mortality relative to their noncongenital heart disease peers** (Maxwell et al., 2013, 2014; Ramamoorthy et al., 2010). The Pediatric Perioperative Cardiac Arrest (POCA) Registry is the best source of information regarding risk stratification. Overall, infants with a functional single ventricle, patients with suprasystemic pulmonary hypertension, patients with left ventricular outflow tract obstruction, and those with dilated cardiomyopathy are considered high risk (Gottlieb and Andropoulos, 2013; Saettele et al., 2016).

Other risk factors include emergency procedures, severe congenital heart disease, single-ventricle physiology, previous surgery within 30 days, perioperative inotropic support, preoperative cardiopulmonary resuscitation, acute or chronic kidney injury, and mechanical ventilation, which have been shown to significantly increase postoperative mortality (Faranoni et al., 2016). Critical evaluation of surgical need is necessary in this complex population.

Renal Abnormalities

Renal disease is a rare but significant cause of morbidity and mortality in children and is an important consideration in children with urologic abnormalities who are in need of surgery. Infants and children younger than 6 years of age typically have kidney insufficiency caused by developmental abnormalities, such as obstructive uropathy, and older children typically have acquired conditions (Bennett and Bromley, 2007). Hematologic implications of chronic kidney disease (CKD) include the potential for anemia, which can alter respiratory function by decreasing oxygen availability, and with more invasive surgeries would require preoperative blood transfusion. Elevations in urea can result in platelet dysfunction, increasing the risk for intraoperative bleeding and resulting in poor nutrition and slow gastric emptying. Cardiac function may also be affected resulting in cardiomyopathy, congestive heart failure, and pulmonary edema (Guruswamy and Barbour, 2015).

Urine output may be normal, or children may have polyuria, oligouria, or anuria affecting total body fluid volumes. Electrolyte abnormalities can occur including hyponatremia, hyperkalemia, hypocalcemia, hyperphosphatemia, and metabolic acidosis. **In the perioperative period, abnormalities such as hyperkalemia can increase the risk for cardiac arrhythmias.**

Preoperatively, laboratory evaluation should include a complete blood count, serum chemistry panel, and coagulation screening. In patients with suspected cardiac or lung abnormalities, a chest x-ray or ECHO and an ECG should be performed (Guruswamy and Barbour, 2015). Antihypertensive and immunosuppressive medications should be continued unless otherwise advised by the nephrologist or the anesthesiologist. Preoperative dialysis is performed if indicated and surgery avoided for 4 to 6 hours after hemodialysis (Guruswamy and Barbour, 2015).

Patients with CKD stage 1 should be treated postoperatively with general pain medications, including nonsteroidal anti-inflammatory drugs (NSAIDs), opioids, and tramadol (Tawfic and Bellingham, 2015). Patients with CKD stage 2 have mild impairment of renal function but are able to excrete drugs and metabolites so do not require medication adjustments (Bailie et al., 2005; Khwaja and Throssell, 2009; Levey et al., 2003; National Kidney Foundation, 2002). They should be monitored for additional renal deterioration caused by perioperative events and the effect of NSAIDs on kidney function (Lee et al., 2007). Patients with stages 3 and 4 CKD have moderate to severe impairment of renal function. **NSAIDs can significantly worsen renal function in children with CKD stages 3 and 4 and should be avoided.** Attention should be given to adjusting analgesic drug dosages based on GFR, and patients should be monitored closely for any sedation effect (Murtagh, 2007; National Kidney Foundation, 2002; Sear, 2005).

Hematologic Disorders

Hemoglobinopathies are among the most common inherited diseases around the world, and there are two main groups that include the thalassemia syndromes, including α- and β-thalassemia and the structural hemoglobin variants HbE, HbC, and the most common HbS or sickle cell disease.

Sickle cell disease is a chronic illness characterized by hemolysis and vasoocclusion caused by irreversible sickling and clumping of the red blood cells. Patients with sickle cell disease have chronic anemia and are susceptible to pain crisis, acute chest syndrome, strokes, splenic sequestration, cardiomyopathy, congestive heart failure, and renal disease (Falk, 1982; Lopez et al., 1973; Marchant and Walker, 2003; Seeler 1972).

Acute chest syndrome, which is the main cause of death during the administration of general anesthesia, occurs postoperatively in approximately 10% of children with sickle cell disease (Delatte et al., 1999; Firth and Head, 2004; Howard et al., 2015; Vichinsky et al., 1995). Preoperative assessment of children with sickle cell disease should evaluate for end-organ damage, including respiratory insufficiency and cardiac problems. Preoperative testing is dependent on the patient but should include a baseline CBC at a minimum (Marchant and Walker, 2003). A preoperative exchange transfusion versus a simple transfusion may be indicated. Important intraoperative factors that should be incorporated into the anesthetic includes maintenance of normothermia, adequate hydration, pain control, and avoidance of hypoxia and acidosis, which all can lead to increased sickling of red blood cells. Tourniquets should be avoided in patients with sickle cell disease.

The most important factor in the perioperative management of children

with sickle cell disease is avoidance of dehydration, especially during the preoperative NPO status. Perioperative fluid management should include intravenous fluid hydration during preoperative fasting and postoperative intravenous fluid support until the patient is tolerating adequate oral intake (Reed and Vichinsky, 1998). Low oxygen levels, vascular stasis, hypothermia, acidosis, and infection should be avoided postoperatively. Adequate pain medication, hydration until oral intake has resumed, and early postoperative ambulation are important. Recommendations for preoperative transfusion should be discussed with the hematologist (Fu et al., 2005; Koshy et al., 1995; Alotaibi et al., 2014).

Oncologic Disorders

Chemotherapy and Perioperative Considerations

Chemotherapeutic drugs have systemic effects, and because most are antiproliferative agents targeting cells that rapidly divide, cardiac, pulmonary, renal, hepatic, gastrointestinal, bone marrow, and neurologic damage is common. Because patients may undergo elective or emergency procedures at any point during chemotherapy administrations, it is important to be aware of the preoperative evaluation needs and the potential side effects of these agents. A detailed drug history is important to understand the exact chemotherapy regime and the potential side effects. Preoperative testing is dependent on the chemotherapy regimen, patient's symptoms, and timing of chemotherapy treatments.

Specific chemotherapy agents have significant toxicity that can impact anesthesia administration. **Bleomycin can result in pulmonary toxicity in 6% to 10% of patients treated with this medication, and it can be fatal in severe cases** (Simpson et al., 1998), **with exposure to high-inspired oxygen levels during anesthesia resulting in pulmonary toxicity** (Donat, 1999). Cardiac toxicity caused by chemotherapy is common and can result in arrhythmias, blood pressure fluctuations, cardiomyopathy, congestive heart failure, and so on. Several chemotherapy drugs are nephrotoxic and may contribute to either acute or chronic renal failure. Similarly, the hematopoietic effects of chemotherapy medications including pancytopenia can result in a decreased oxygenation, increased risk for hemorrhage, and sepsis.

Pheochromocytoma

Pheochromocytomas are rare neuroendocrine tumors of the adrenal medulla that synthesize and store catecholamines, specifically norepinephrine and epinephrine, which can produce potentially fatal complications when stimulated by anesthesia induction or surgical manipulation. Preoperative and intraoperative management of hypertension is essential for a safe anesthetic. A detailed discussion of pheochromocytomas is covered in this text. **In brief, for children medications are given with a goal of blood pressure reduction of <50th percentile for age and height, and this is often achieved with an alpha-2 receptor antagonist before beta blockade to prevent the likelihood of severe hypertensive crisis from unopposed alpha-receptor stimulation** (Agrawal et al., 2014; Bravo and Tagle, 2003; Ludwig et al., 2007; Romero et al., 2015). Some protocols recommend that patients be placed on a high-sodium and high–fluid-intake diet. These investigators report this regimen helps prevent intraoperative and postoperative hypotension (Agrawal et al., 2014; Bravo and Tagle, 2003; Ludwig et al., 2007; Romero et al., 2015). Additionally, they recommend hospital admission 24 to 36 hours preoperatively for pharmacologic management and intravenous fluid hydration. **Postoperatively hypoglycemia can occur because of acute catecholamine reduction and resulting elevated serum insulin levels. Glucose levels should be monitored** (Hack, 2000).

Spina Bifida

Patients with spina bifida can have multiple challenges because of their underlying neurologic abnormalities, anatomic abnormalities, and the possible associated comorbidities. It is important to consider all aspects during surgical planning. Approximately 90% of infants born with spina bifida have hydrocephalus or will develop hydrocephalus over time. In some cases, a ventriculoperitoneal (VP) shunt may be required. A focused physical examination can identify papilledema or abnormal cognitive function (Whitney et al., 2016). In the perioperative period, adequate shunt function is necessary to avoid intraoperative complications (Whitney et al., 2016). If poor shunt function is suspected, elective operative cases should be rescheduled.

Recent studies report that 53% of patients with spina bifida have some degree of scoliosis (Mummareddy et al., 2017). Spinal defects can alter the thoracic capacity and affect lung function. Because pulmonary disorders may not be clinically evident, if patients are being considered for surgery, respiratory function testing may be helpful. In the operating room, it is important to understand the spinal abnormalities and to evaluate for possible pressure points to ensure that adequate padding is in place for pressure sore prevention. For patients with severe skeletal deformities, a postoperative air mattress may be helpful when extended hospitalizations are anticipated.

Patients with high-level neural tube defects with lesions between T5 and T8 are at an increased risk for autonomic dysreflexia, a potentially life-threatening syndrome caused by a dysregulated *sympathetic* discharge reflex. A sympathetic trigger such as noxious stimuli can lead to severe complication including uncontrolled hypertension, bradycardia, stroke, and potentially death. Spina bifida patients may have anaphylactic latex allergy. Symptoms include bronchoconstriction, vasodilation and subsequent hypotension, increased capillary permeability, coronary vasoconstriction, and myocardial depression. Without immediate recognition and treatment, severe cases can be fatal.

Pain control in patients with spina bifida can be challenging, particularity in patients with shunted hydrocephalus. Placement of epidural catheters in patients with spina bifida has been reported in the adult literature (Tidemarsh and May, 1998), and a recent abstract presented by Roth et al. reported safety of thoracic-level epidural catheter in select spina bifida patients (Roth et al., 2017). Although experience at our institution is smaller, five patients with spina bifida have undergone perioperative epidural catheter placement with good pain control and no long-term complications. More studies are needed to evaluate the safety of this pain-control option. Other pain options include regional blocks and incision infusion catheter placements (Chalmers et al., 2015) as well as standard pain control options such as patient-controlled analgesia (PCA) and intravenous medications.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) compromises a group of autosomal recessive disorders of cortisol biosynthesis. The cause in 95% of cases is 21-hydroxylase deficiency. This enzyme defect results in cortisol deficiency, which may or may not be associated with aldosterone deficiency and excess androgens. The severity of CAH can vary from severe to mild and is most often subclassified as salt losing or non–salt losing. Deficiency of aldosterone in the salt-wasting form results in renal sodium losses, hypovolemia, and hyperkalemia. Cortisol deficiency results in poor cardiac contractility with decreases in vascular tone (Minette et al., 2013).

During times of stress, such as surgery, patients with classic CAH are unable to mount an appropriate cortisol response. In major physical stress, such as surgery, patients require a stress dose of steroids, preferably given intravenously with intravenous fluids (Claahsen-van der Grinten et al., 2011). Epinephrine and cortisol deficiency can result in hypoglycemia with fasting, so glucose-containing fluids should be administered, and children should be monitored for low glucose levels (Merke and Bornstein, 2005).

Key Points

- Anesthesia risks include postoperative nausea and vomiting, bronchospasam, laryngospasm, stridor, emergence delirium, and postanesthesia maladaptive behaviors.
- NPO violation significantly increases the risk for gastric aspiration and pneumonitis.
- Premature infants have a significantly increased risk for perioperative complications.
- Spina bifida patients have the potential for multiple comorbidies, which should be considered perioperatively.
- Autonomic dsyreflexia is life threatening. Pediatric urologists should know signs and symptoms of onset.

Acute Preoperative Events

Sepsis

Pediatric sepsis is a leading source of morbidity, mortality, and health care costs in infants and children (Centers for Disease Control and Prevention, 2017). The overall mortality rate is 0% to 5% in previously healthy children (Booy et al., 2001; Nhan et al., 2001) and 10% in chronically ill children with septic shock (Kutko et al., 2003). There are multiple etiologies for sepsis/systemic inflammatory response syndrome, but infections are a common cause. In cases of urologic sepsis, an infective etiology is the likely source. Broad-spectrum agents may be used initially to cover all pathogens while cultures are pending. If cultures cannot be obtained, antibiotics should not be withheld and should be started immediately.

The first 6 hours of resuscitation of septic patients, referred to as the "golden hours," are crucial and frequently coincide with the time for emergency surgery (Dellinger et al., 2008; LeDoux et al., 2000). Aggressive fluid administration with or without vasopressor support is necessary. **Supplemental oxygen therapy is valuable in severely septic patients, even if they do not have signs of respiratory distress** (Schuz-Stubner et al., 2008). If large intraoperative volume losses are anticipated during the surgical procedure, this should be discussed and preparations should be made, including blood type and cross-match, and appropriate intravascular volume resuscitation devices should be placed. Evaluation of serum chemistries, complete blood counts, and coagulation levels should be performed. Patients in septic shock will require the intensive care unit for postoperative management. For pain control, peripheral nerve blocks may be effective and avoid the systemic effects of opioids in a hemodynamically unstable patient. Spinal and epidural anesthesias are generally avoided in patients in shock because of hemodynamic effects and potential coagulopathies (Guay, 2006; Schuz-Stubner et al., 2008).

Trauma

Traumatic injuries continue to be a major cause of death in US children between 1 and 14 years of age (Heron et al., 2009). Often these children require surgical intervention, especially in high-impact traumas, when the risk for urologic injury is increased. In emergent cases, a focused history and physical examination should be performed.

Imaging evaluation may be needed but should not delay emergency life-saving intervention. Laboratory testing is useful, but blood can be obtained in the operating room setting to prevent delays and should include a complete blood count, electrolytes, type and cross-match, coagulation factors, and possible arterial blood gas, depending on the clinical scenario (Hymel et al., 1997; Linzer, 2010).

Pediatric trauma victims should always be considered as full-stomach patients, and rapid-sequence induction is the gold standard (Sagarin et al., 2002). The operating room must be kept as warm as possible during trauma cases to avoid complications related to hypothermia, such as coagulopathies, especially in infants and younger children (Bone et al., 1992). Postoperative pain control is important and may help reduce anxiety and fear in children (Schechter et al., 1997). Oral, rectal, and intravenous acetaminophen can be used. Ibuprofen is also effective (Clark et al., 2007). Opioids should not be withheld in general, unless there are concerns that preclude administration of these medications (Berde and Sethna, 2002).

Upper Respiratory Tract Infection

URTI is the most common nonpreventable cause of surgery cancellations (Bathla et al., 2010). Infection-induced inflammation of the upper respiratory mucosa will result in the airway developing a hyperreactive state with increased secretions and increased sensitivity to irritants, including those used for anesthesia. **This increase in hyperreactivity can persist for 6 to 8 weeks following infection and result in an increased risk for perioperative respiratory adverse events, including laryngospasm, stridor, bronchospasm, cough, breath-holding, desaturation, bradycardia, atelectasis, and pneumonia** (Tait and Malviya, 2005; Tait et al., 2001). If children have or have had a recent URTI, surgeons and anesthesiologists must evaluate the patient and determine whether to postpone surgery or proceed with caution. Studies have shown that a laryngeal mask results in less perioperative airway complications than an endotracheal tube in children with a URTI (Tait and Pandit, 1998).

Urinary Tract Infection (UTI)

The American Urological Association (AUA) guidelines state that, for urologic surgery where there is an existing infection such as bacteriuria at the time of endoscopic procedures, the infection should be eradicated before surgical manipulation with a therapeutic course of antibiotics in an attempt to sterilize the operative field (AUA, 2018).

In spite of these guidelines, there are very few studies that address the need for preoperative urine evaluation in pediatric urologic surgery or the need to delay surgery in the presence of UTIs. However, studies have clearly shown that preoperative UTI, particularly if recurrent, is recognized as a high-risk factor for postoperative infection (Grabe, 2010; Hamasuna et al., 2004; Matsumoto et al., 2007; Yamamoto et al., 2005). Based on these studies and on current recommendations, preoperative urine cultures should be obtained preoperatively if a sterilized field is required and can be obtained. If a UTI or bacteremia is present in surgical cases in which the lower or upper urinary tract will be surgically manipulated, antibiotics should be administered and the surgical procedure rescheduled until the urine is sterile.

In some cases, such as an indwelling catheter or infected stones, sterilization of the urine may not be possible. In these cases, perioperative urine culture may be beneficial to document microbial organisms and determine antibiotic sensitivity when a postoperative infection develops. Although there are no standardized recommendations for patients with neurogenic bladder, given the complexity of surgical reconstruction coupled with guidelines, common practice is to obtain a preoperative urine culture and therapeutically treat based on microbial sensitivities. More studies are needed to develop specific guidelines for preoperative evaluation of urine for pediatric urologic procedures.

Nonspecific Fever

The most common cause of perioperative fever involves an infectious etiology. In children, this is typically associated with URTI, which has a viral etiology in 95% of cases, and allergies and rhinitis can also play a role (Tait and Malviya, 2005). Patients undergoing blood transfusion can also have febrile events up to 1 week after transfusion (Gilliss et al., 2011). Allergic reactions to drugs and noninfective etiologies such as autoimmune disorders, malignancy, or other medical comorbidities can also contribute to perioperative nonspecific fevers (Adnet, 2000; Pile 2006). When children present in the perioperative setting with a nonspecific fever, the anesthesiologist and surgeon need to decide whether to cancel the case or continue with the surgery. The physical examination will play an important role in this decision.

Key Points

- Antibiotics are the mainstay of sepsis treatment and should be administered as soon as possible. Culture should be obtained if possible.
- Urine cultures should be obtained preoperatively when indicated, and positive cultures should be treated with antibiotics based on sensitivities.

ERAS Protocols

The goal of the ERAS pathway is to expedite patient recovery to baseline function by maintaining perioperative organ function and limiting postoperative stress (George et al., 2018). The ERAS pathway employs several components, which include avoiding prolonged fasting, early enteral nutrition and mobilization, preoperative oral carbohydrate loading, and enhanced efforts in patient education. Anesthesia strategies include standardization of anesthetic-related medications, antiemetics, and standardized intraoperative fluid management. These protocols have been found to decrease length of hospital stay, the number of complications, and hospital cost in the adult population (Adamina et al., 2011; Auyong et al., 2015; Geltzeiler et al., 2014; He et al., 2015; Kagedan et al., 2015; Miller et al., 2014; Stowers et al., 2015; Tang et al., 2013; Thiele et al., 2015).

Two evidence-based reviews of ERAS pathways in the pediatric population have highlighted the potential value of this approach. One review concluded that ERAS-like pathways applied to the appropriate pediatric patients may decrease opioid use and reduce length of hospital stay (Shinnick et al., 2016). Similarly, Pearson and Hall reviewed nine studies and the elements in the ERAS pathway including limited use of postoperative nasogastric tubes with postoperative feeding, limited use of urinary catheters, early mobilization, and nonopioid pain management. This group reported earlier return of bowel function with reduced time to oral feeds and reductions in length of hospitalization (Pearson and Hall, 2017). Recently, a prospective study comparing pediatric patients undergoing urologic reconstructive surgery with postoperative management following a specific ERAS protocol were compared with historical patients. Patients managed on the ERAS protocol had a decreased length of stay and a decrease in 90-day complications without increased readmissions, reoperations, or emergency department visits (Rove et al., 2018). Based on these reviews and this recent prospective study, it appears that ERAS protocols in children are beneficial and should be developed for the pediatric surgical population.

Intraoperative Considerations

Preoperative Antibiotics

Surgical site infections (SSIs) are a major cause of increased morbidity, mortality, readmissions, and extended length of hospitalization (de Lissovoy et al., 2009; Magill et al., 2014). The guiding principles for surgical antibiotic prophylaxis include administration of an antimicrobial agent intended to reduce the risk for postoperative local and systemic infection as determined by the ability of the patient to respond to bacterial invasions, the likelihood of bacterial invasions, and the potential morbidity related to the infection and benefit, which outweighs the risk associated with antibiotic administration (AUA, 2018).

Administration of antibiotics preoperatively in children is guided by recommendations in the adult literature. Recommendations by urologic procedure are available at http://www.auanet.org/guidelines. Commonly used antimicrobials, dosages, and redosing intervals used for surgical prophylaxis are shown in Table 26.2. Unfortunately, there is limited data on antimicrobial prophylaxis, specifically for pediatric patients undergoing urologic procedures, and, interestingly, common practices are undergoing evaluation and changes (Baillargeon et al., 2014; Chan et al., 2017; Rangel et al., 2011; Smith et al., 2017). Timing of antibiotics should allow for adequate serum and tissue concentrations before incision (Bratzler et al., 2004; Galandiuk et al., 1989). **Administration of the preoperative antibiotic dose should occur within 60 minutes of surgical incision** (Bratzler et al., 2004; Steinberg et al., 2009). Because of prolonged infusion time, vancomycin and fluoroquinolones should be administered within 120 minutes before incision (Bratzler et al., 2013).

TABLE 26.2

Common Antimicrobials Used for Surgical Prophylaxis

ANTIMICROBIAL	RECOMMENDED PEDIATRIC DOSAGE	INTRAOPERATIVE DOSING INTERVAL (hours)
Ampicillin-Sulbactam	50 mg/kg of ampicillin	2
Ampicillin	50 mg/kg	2
Aztreonam	30 mg/kg	4
Cefazolin	30 mg/kg	4
Cefuroxime	50 mg/kg	4
Cefotaxime	50 mg/kg	3
Cefoxitin	40 mg/kg	2
Cefotetan	40 mg/kg	6

Cetriaxone	50–75 mg/kg	NA
Ciprofloxacin	10 mg/kg	NA
Clindamycin	10 mg/kg	6
Ertapenem	15 mg/kg	NA
Fluconazole	6 mg/kg	NA
Gentamicin	2.5 mg/kg	NA
Levofloxacin	10 mg/kg	NA
Metronidazole	15 mg/kg Neonates <1200: 7.5 mg/kg	NA
Moxifloxacin	10 mg/kg	NA
Piperacillin-tazobactam	Infants 2–9 months: 80 mg/kg of piperacillin Children >9 months and <40 kg: 100 mg/kg piperacillin	2
Vancomycin	15 mg/kg	NA

Common side effects of antibiotics are allergic reaction, including anaphylaxis and gastrointestinal symptoms (nausea, vomiting, pain), *Clostridium difficile* infection, and antibiotic resistance.

The presence of comorbidities such as renal or liver insufficiency may affect recommended dosages, which may require dosage adjustment.

Modified from Bratzler DW, Houck PM; Surgical Infection Prevention Guideline Writers Workgroup. Antimicrobial prophylaxis for surgery: an advisory statement from the National Surgical Infection Prevention Project. *Am J Surg.* 2005:189:395.

Intraoperative and Perioperative Fluid Management

Both restrictive and liberal intraoperative fluid regiments have led to complications, so the pediatric anesthesiologist will aim to provide optimal fluid management based on the patient's fluid deficit, maintenance fluid requirements, and intraoperative fluid losses. Fluid deficit requirements will take into account length of NPO status and the presence of a bowel prep. Maintenance requirements can be calculated by the 4-2-1 rule, originally described in 1957 but still widely used today. The 4-2-1 rule is 4 mL/kg/h for the first 10 kg, 2 mL/kg/h for the second 10 kg, and 1 mL/kg/h for every kilogram greater than 20 kg. For example, a 22-kg patient's maintenance requirement will be 62 mL/h (Holliday and Segar, 1957). There are numerous studies looking at the best crystalloid and colloid replacement. However, overall there is no definitive evidence-based preference as long as optimal fluid management is achieved. Some investigators argue that lactated Ringer's solution with balanced electrolytes are superior to normal saline, which can lead to dilutional acidosis (Lobo and Awad, 2014). There are some caveats regarding fluid therapy, such as limiting dextrose-containing maintenance fluid in neonates less than 2 to 4 months of age because of their immature livers, avoiding lactated fluids in patents with mitochondrial diseases, and avoiding potassium-containing fluids in dialyzed patients, to name a few.

During the postsurgical period, patients should continue maintenance fluid therapy until they can tolerate adequate fluid and nutritional intake by mouth. Historically, hypotonic fluid, such as .45%, was recommended for postoperative fluid management. However, recent studies have found that although the incidence of hyponatremia (<135 mmol/L) in the pediatric postsurgical patient is relatively low (Au et al., 2008; Cladis et al., 2011; Eulmesekian et al., 2010), there is consistent consensus that postoperative patients are at an increased risk for low serum sodium levels. One reason for the development of hyponatremia is the surgically induced stress-related increased release of antidiuretic hormone (ADH). ADH is typically produced by the hypothalamus and subsequently released from the posterior pituitary gland. ADH works in the collecting duct to increase the presence of aquaporin-2 channels, which ultimately increases water permeability and water reabsorption. ADH is normally produced in response to osmolality changes. However, multiple perioperative events such as nausea, pain, and hypoxia can increase release as well (Bailey et al., 2010). Because there is an increased risk for postoperative hyponatremia and the sequel associated with it, current recommendations include the use of isotonic fluid, such as 0.9% NS or lactated Ringer's solution, with dextrose (D_5) for maintenance therapy in the healthy postsurgical child (McNab et al., 2014). If normal saline is selected, potassium should be added. Potassium should be added at 10 mEq/L if <10 kg and 20 mEq/L if >10 kg. Premature infants have immature kidneys, which are unable to handle large solute loads, and maintenance intravenous fluids should be guided to minimize impact on the kidneys.

Anaphylaxis

Perioperative anaphylaxis is a clinical condition that is more likely to occur during adulthood than during childhood and primarily occurs within minutes following anesthetic induction. Neuromuscular blocking agents and β-lactam antibiotics are the main triggers involved in cases of perioperative anaphylaxis.

Latex-induced allergy can occur but is now less common. Anaphylaxis results in cardiovascular collapse with tachycardia, hypotension, severe bronchospasm, and hives. **Management includes immediate cessation of the drug or suspected culprit, 100% oxygen, Trendelenburg positioning, aggressive fluid therapy, albuterol, and epinephrine.** Surgery should be postponed (Dewachter et al., 2015).

Malignant Hyperthermia

Malignant hyperthermia is a rare but potentially fatal hypermetabolic disorder that is triggered by succinylcholine and inhaled anesthetics, excluding nitrous oxide. **The initial signs of malignant hyperthermia include unexplained hypercarbia, sinus tachycardia, masseter muscle spasm, and hyperthermia. Later signs include severe metabolic acidosis, peaked T waves from hyperkalemia, generalized muscle rigidity, and rhabdomyolysis**.

If a patient is determined to be susceptible to malignant hyperthermia, the patient should be scheduled as a first-start case to avoid exposure to inhaled anesthetics leftover from the previous case. Activated charcoal filters decrease the length of time needed to “prepare” the machine from 20 to 104 minutes to 90 seconds (www.MHAUS.org).

If a malignant hyperthermic event is suspected, all triggering agents should be stopped, backup support should be requested, dantrolene should be obtained, and the patient should be disconnected from the anesthesia machine until it is replaced with a clean machine. An arterial line and Foley catheter should be placed. A team member can be instructed to call the 24-hour malignant hyperthermia hotline at 1-800-644-9737 to obtain expert help at any time during the event. Patients should be admitted for 24 to 48 hours for continued treatment, supportive care, and for the possibility of recrudescence. Hyperkalemia and cardiac arrest should be treated aggressively. A cognitive aid (https://www.ncbi.nlm.nih.gov/books/NBK1146/figure/mhs.F2/) is helpful in any emergency situation to ensure that all treatment and supportive options are being utilized. In spite of the much lower mortality rate of 5% in recent years, there is still significant morbidity related to malignant hyperthermia, so quick recognition and aggressive treatment is necessary. All incidences of malignant hyperthermia should be reported to the malignant hyperthermia registry (www.MHaus.org/registry), which can be accessed for data collection.

Laparoscopic Procedures

Minimally invasive surgery was introduced to pediatric urology more than 30 years ago with the description of diagnostic laparoscopy for nonpalpable testes (Cortesi et al., 1976). There are multiple benefits to laparoscopy and robotic-assisted laparoscopic surgery in children, so utilization has significantly increased. Even though laparoscopy is well tolerated in children, there are anatomic and physiologic challenges in the pediatric population that should be considered.

In children, chest wall compliance is increased and functional residual capacity is decreased. Decreased chest wall compliance in the presence of increased airway pressures caused by CO_2 insufflation can result in oxygen desaturation (Wedgewood and Doyle, 2001). Pneumoperitoneum also influences cardiovascular function, but the overall impact is minimal in children with normal cardiac function (Gentili et al., 2000). There have been concerns about renal and brain perfusion, but to date, there has been no evidence to conclude there are detrimental effects to these organs (Bellon et al., 2018; Gómez Dammeier et al., 2005; Maesani et al., 2016).

Proper positioning is important in laparoscopic cases to ensure adequate access to the organ of interest. All pressure points should be padded to prevent nerve injuries. **An axillary roll should be used to prevent brachial plexus compression when operating on a patient in the lateral decubitus position, and the neck should be maintained in a neutral position in alignment with the spine (Martin, 1987).** To avoid lower-extremity nerve injuries, the dependent leg is flexed and a cushion is placed between the knees to minimize pressure on these areas.

Multimodal analgesia has been shown to speed up postoperative progress with the use of both nonopioid analgesics (NSAIDs) and opioid agents (Brasher et al., 2014; Michelet et al., 2012, 2016). Regional analgesia may decrease the side effects of opioid agents.

One of the most important considerations in children undergoing laparoscopic procedure is the possibility of a CO_2 embolus. This event occurs during insufflation when a high volume of CO_2 enters the venous system resulting in obstruction to the outflow of the right ventricle and pulmonary circulation. This results in sudden oxygen desaturation and cardiovascular collapse. Decreasing end-title CO_2 coupled with a mill-wheel murmur are classic findings (Gutt et al., 2004). **Treatment includes placement of the patient in the left lateral decubitus (right side up) and Trendelenberg positions and aspiration of the air embolus through a central line if one is in place** (Gutt et al., 2004).

Intraoperative Pain Management

The choice of intraoperative pain management techniques are dependent on patient factors, surgical factors, and comfort level of the pediatric anesthesiologist. Epidural analgesia is a good choice for both intraoperative and postoperative pain management for open surgical procedures with large incisional sites. Epidurals can be safely placed in patients as small as 2 kg in the hands of experienced pediatric anesthesiologists (Long et al., 2016).

Neuraxial and regional anesthesia is safely performed in anesthetized versus awake pediatric patients, and this is the standard approach (Taenzer et al., 2014). The use of regional or neuraxial analgesia during the intraoperative period allows for avoidance or minimized use of opioids. Decreased use of opioids during the intraoperative period can also be achieved by the use of multimodal analgesia. Acetaminophen, a Cox-2 inhibitor, and gabapentin can be administered preoperatively in certain patient populations. Intravenous acetaminophen can also be administered during the intraoperative period. The current trend is to use intravenous as opposed to rectal acetaminophen during the intraoperative period because the absorption of rectal acetaminophen is so unpredictable (Anderson et al., 1995; Birmingham et al., 1997; Houck et al., 1995; Howell and Patel, 2003; Khalili et al., 2016).

Intravenous lidocaine has been shown to be beneficial as a multimodal analgesic approach intraoperatively, with some studies advocating for its use to continue for 24 hours during the immediate postoperative course (Kranke et al., 2015; McCarthy et al., 2010). Intravenous lidocaine is used in a majority of ERAS protocols. It is important to know if an intravenous lidocaine infusion is part of the intraoperative anesthesia plan to ensure that it is included in the total local anesthesia calculations to avoid toxicity.

Other adjuncts that are used for intraoperative pain management include intravenous ketamine and dexmedetomidine infusions. Both can decrease the overall narcotic need and improve postoperative analgesia. Dexmedetomidine is one of the few drugs used in anesthesia that has been shown in animal models to be protective against neurocognitive effects (Perez-Zoghbi et al., 2017). Intravenous ketorolac is an option for multimodal analgesia and has been safely used in neonates less than 6 months of age but is commonly reserved for infants 6 months and older with normal renal function.

It is important to discuss pain management with the anesthesiologist for intraoperative and postoperative pain management.

Key Points

- Antibiotics are the mainstay to prevent SSIs. Selection of antimicrobial should consider the site and potential source of infection.
- Interoperative complications can occur. Pediatric urologists should be knowledgeable in recognition and treatment.

Postoperative Management

Immediate Postoperative Management

During the immediate postsurgical period, attention is focused on respiratory and cardiovascular status because of the risk for adverse events. **Respiratory events include hypoxia, airway obstruction, laryngospasm, bronchospasm, postobstructive pulmonary edema, and aspiration**. The incidence of adverse events are increased in patients who are intubated, ASA 3-4, and age less than 1 year of age, children with a respiratory pathology, premature infants, and those with current or recent upper respiratory infection (Murat et al., 2004). Multiple intubation attempts can lead to airway edema and present as stridor. Laryngospasm can result in the need for reintubation if positive pressure ventilation and propofol-induced relaxation of the vocal cords are not successful. Bronchospasm can be treated with albuterol/atrovent nebulizers but if severe, treatment may require epinephrine, steroids, magnesium, and continuous albuterol treatments. Depending on the severity these patients may need to be admitted for continual treatment and airway support.

Children with congenital cardiac disease are at a higher risk for a cardiac adverse event (Saettele et al., 2016). Fortunately, the risk for postoperative pediatric cardiac arrest in the noncardiac population is rare with an incidence of less than 1 per 100,000 pediatric anesthetics. (Morray et al., 2000; Zgleszewski et al., 2016). When a cardiac arrest does occur in the postoperative setting, most are in children younger than 5 and most are deemed preventable (Christensen and Voepel-Lewis, 2017; Christensen et al., 2013, 2017). This highlights the necessity of continual vigilance and early recognition and treatment of adverse events in the pediatric postanesthesia care unit (PACU).

Children, especially between the ages of 2-8 years, can emerge from anesthesia with restlessness, agitation, delirium, combativeness, and an inability to be consoled. This phenomenon is referred to as emergence delirium and has a reported incidence of 10-80%, depending on the study (Voepel-Lewis et al., 2003). Typically this event occurs within the first 30 minutes and is self-limited. However, it is very disturbing to care providers and parents and can be dangerous to the child resulting in self-injury, removal of Foley catheters and intravenous catheters, and damage to the surgical site. It is important to rule out pain and normal behavior (e.g., temper tantrum) for the particular patient. There is a scoring system for emergence delirium, the Post Anesthesia Emergence Delirium (PAED) scale, that can be used to help differentiate emergence delirium from pain or other etiologies (Sikich and Lerman, 2004). The most distinguishing quality of emergence delirium is the inability to recognize the patient's surroundings or parents. Patients who are highly anxious preoperatively are at a higher risk for emergence delirium. Treatment may involve low-dose bolus of propofol by the anesthesiologist with immediate vigilance for airway compromise after administration. Dexmedetomidine, fentanyl, and clonidine may be used as well. It is important to discuss the possible risk for emergence delirium with the parents or care providers preoperatively. If patients are deemed high-risk, anesthesiologists may preemptively treat before the anesthetic effect has ended.

Postanesthesia Care Unit and Pain Management

Postoperative pain can be extremely distressful to the patient, care provider, and parents. The anesthesiologist should not leave the patient's beside in the PACU until there is a postoperative pain plan in place. Pain assessment and management has been discussed in an earlier section and the institutional pain scale should be used to evaluate pain with titration of both narcotic and non-narcotic pain medications. PCA and PCA by proxy can be initiated in the PACU for patients admitted for surgery when this is the plan for pain control. PCAs can be safely used in patients as young as 4 years old who are cognitively appropriate, and PCA by proxy (parent- or nurse-administered PCAs) are available in many children's hospitals. If a regional or neuraxial technique is used, then the anesthesiologist must ensure this is functioning well. Patients should not be discharged from the PACU until adequate pain control has been achieved.

Discharge from the PACU can be achieved once the patient returns to their baseline function with normal hemodynamics. The Aldrete score and Post-Anesthetic Discharge Scoring System (PADSS) is often utilized to determine readiness to leave the PACU. (Biedermann et al., 2014; Marley and Moline, 1996; Marshall and Chung, 1999). An anesthesiologist should provide a brief postanesthesia evaluation note that must include respiratory function, cardiovascular function, mental status, temperature, pain, nausea, vomiting, and postoperative hydration. Documentation is required by The Centers for Medicaid and Medicare, which must be completed within 48 hours of the anesthetic.

Inpatient and Outpatient Postoperative Pain Management

Studies show that approximately 80% of surgical patients have postoperative pain, which is most often described as moderate to severe (Apfelbaum et al., 2003). **Appropriate postoperative pain management in the pediatric patient is a major concern because studies show pain management in children is often inadequate because of challenges with pain assessment and concerns about opioid side effects** (Astuto et al., 2007; Lee and Jo, 2014; Morton, 2007; Segerdahl et al., 2008; Taylor et al., 2008). Poor pain management can increase the risk for complications, increase recovery time, and increase morbidity and mortality (Katz et al., 1996; Kehlet and Holte, 2001; Sharrock et al., 1995) in the adult population, which is extrapolated to the pediatric population, prompting attention to adequate pain management.

Expectations for pain including the expected quality and duration of postoperative pain should be discussed preoperatively with the patient and/or family. **For pain management, both inpatient and outpatient pain management should include a multimodal approach.** For surgical pain, a combination of acetaminophen and NSAIDs is the basis for the treatment. This combination has been shown to decrease opioid use by 30% to 40% (Michelet et al., 2012; Wong et al., 2013). Opioids can be used for breakthrough pain but are commonly associated with side effects such as nausea, pruritus, constipation, and respiratory depression. **Of note, regulatory authorities warn against using codeine in children with absolute contraindicated use following tonsillectomy for obstructive sleep apnea** (USDA, 2017). During the initial postoperative period, patients should be on a scheduled pain regimen to preemptively address pain. Treating pain as needed has been shown to be inadequate for quality postoperative pain control (Simons and Moseley, 2008; Sutters et al., 2010). Table 26.3 shows the most common narcotic and non-narcotic analgesics used in pediatrics.

TABLE 26.3

Pediatric Pain Medication Dosages and Intervals

NARCOTIC	ORAL DOSAGE PER kg	IV DOSAGE PER kg	FREQUENCY	PCA DOSAGE PER kg
Morphine	0.3 mg/kg	0.05–0.1 mg/kg	Every 3–4 hours	0.02 mg/kg every 10 minutes +/− basal 0.02 mg/kg/h
Hydromorphone	0.04 mg/kg	0.01 mg/kg	Every 3–4 hours	0.004 mg/kg every 10 minutes +/− basal 0.002–0.004 mg/kg/h
Fentanyl[a]	NA	0.5–1 mcg/kg	Every 30–60 minutes	0.5 mcg/kg every 6 minutes +/− basal 0.5 mcg/kg/h
Oxycodone	0.1 mg/kg	NA	Every 4 hours	NA
Codeine[b]	Not recommended	NA	NA	NA
Methadone[c]	0.1–0.2 mg/kg	0.1 mg/kg	Every 12–24 hours	NA
NON-NARCOTIC	**ORAL DOSAGE PER kg**	**IV DOSAGE PER kg**	**FREQUENCY**	**NOTES**
Acetaminophen	15 mg/kg	>2 years: 15 mg/kg	Every 6 hours	IV FDA-approved >2 years; <2 years lower dosages have been used. Consult Pediatric Anesthesia <2 years
Ibuprofen[d]	10 mg/kg	NA	Every 8 hours	
Ketorolac[d]	NA	0.5 mg/kg (max 30 mg)	Every 8 hours	0.1 mg/kg loading dose (max 30 mg) × 1. Use limited to 72–96 hours because of renal toxicity
Celecoxib[e]	2–4 mg/kg	NA	Every 12 hours	Max dose 200 mg twice a

				day
Naproxen[f]	5 mg/kg	NA	Every 12 hours	Max dose 500 mg twice a day
Tramadol	1 mg/kg	Not available in US	Every 6 hours	
Gabapentin	5 mg/kg/day titrated to max 35 mg/kg/day	NA	Every 8 hours	Indicated for neuropathic pain. Because of drowsiness, titrate every 2–3 days to maximize tolerated dose
Lyrica	5–10 mg/kg/day	NA	Every 12 hours	Neuropathic pain if gabapentin failure

[a] Fentanyl has a short half-life and is not ideal for sustained pain but can work well to help control acute pain of short duration such as procedural pain. Also can be given intranasally, 1–2 mcg/kg.

[b] Codeine has a black box warning for patients who cannot convert it to morphine (no analgesic benefit) and patients who are ultraconverters and convert a dangerous amount to morphine resulting in death.

[c] Long half-life, and can accumulate causing respiratory depression and death, and possible cardiovascular events in children with prolonged QT syndrome, so ECG required. Consider consultation with a pediatric pain expert before administration.

[d] Ibuprofen and ketorolac are not recommended <6 months of age.

[e] Celecoxib is only FDA-approved for juvenile idiopathic/rheumatoid arthritis >2 years and 10 kg.

[f] Naproxen is only for children >2 years of age.

Opioid Use in Children

Opiate overdose and abuse in children and adolescents frequently results from access to unused pain medications in the household. Currently there are no standard guidelines in pediatric urology for optimal opioid prescriptions, and recent studies have shown that without a standardized protocol, opioid over-prescription rates may be as high as 64% (Garren et al., 2019). Studies also show that decreasing prescribed opioid quantity by 50% can be done without impacting pain control in the postoperative pediatric urology patient (Cardona-Grau et al., 2019). Also concerning is a recent study from our institution that found that up to 62% of patients had leftover opioid medications, with 78% of families failing to dispose of excess opioids after resolution of post-surgical pain (Garren et al., 2019). Therefore it is important to prescribe an adequate number of opioids, ideally without excess, and parents and patients should be educated on the proper storage and disposal of unused narcotics. Our institution has implement educational handouts, which include pain scales and recommended treatment for each level, storage recommendations for opioids, and information about proper disposal. We have also implemented narcotic dropboxes, where patients can dispose of their unused medications. Additionally, we are trialing envelopes containing a substance that will make the narcotics unpalatable. Additional information on the proper disposal of opioids can be found at https://www.fda.gov.

A multimodal approach to pain management not only consists of various drugs but also consists of nonpharmacologic interventions such as distraction with music or art therapy, hypnosis, and/or acupuncture. These techniques can be incredibly valuable, especially in patients with chronic pain conditions.

In addition to pain management, it is imperative to utilize physical therapy to enhance early mobilization. Early postoperative fatigue has several etiologies including noise, medication, and the inflammatory response. Studies have shown that late fatigue results in loss of muscle mass, weight loss, and weakness (Kehlet and Rosenberg, 1997). Both at home and in the hospital setting, sleep hygiene is essential. For children, this includes a set bedtime, avoiding caffeine after 6 PM, and avoiding the use of electronics at bedtime. Melatonin and trazodone are both non–habit-forming and should be considered if sleep is an issue.

Key Points

- Perioperative complications most often occur in the immediate postoperative period.
- Team members should be aware of potential postoperative complications and monitor patients for these potential events after surgery.
- Postoperative pain control is important for optimal surgical outcomes. A multimodal drug approach is recommended.
- Proper administration and disposal of unused narcotics are necessary to prevent overdoses with these medications.

Principles of Laparoscopic and Robotic Surgery in Children

Thomas Sean Lendvay MD, FACS, Jonathan Scott Ellison MD

Ever since the first report of laparoscopic nephrectomy in 1993 and robotic prostatectomy in 2002, urologists have been on the forefront of minimally invasive surgery (MIS). As technology has advanced, so too have the broadened indications for MIS. Perhaps in no other subspecialty of urology is this truer than for pediatric urology, where smaller working spaces and a focus on reconstructive rather than extirpative procedures demand specific technical considerations. Minimally invasive approaches have become standard practice for many commonly performed pediatric urologic procedures. The pediatric urologist must therefore be familiar with several aspects of MIS, including risk-benefit considerations, physiologic implications, unique complications, state-of-the-art technology, and patient selection criteria to optimize patient outcomes.

Because pediatric urology manages a wide variety of congenital anatomic abnormalities, the pediatric urologist applying MIS technologies needs to be nimble, creative, and resourceful. A number of innovations in MIS have spawned from pediatric urologists recognizing “better” ways to apply MIS in our pediatric patients. Our sutures are smaller and tissues are more delicate, thus we have pushed the envelope on the mechanical and technical limitations of MIS technologies. Furthermore, pediatric urologists have championed methods to simulate and evaluate pediatric surgery in an effort to drive improved patient outcomes. In this chapter, we discuss advantages and disadvantages of MIS in children; applications; physiologic considerations of the pneumoperitoneum in children; patient selection; various approaches and instrumentation; complications of MIS in children; and how pediatric MIS is being simulated, taught, and evaluated.

Advantages and Disadvantages of Minimally Invasive Surgery

When counseling families about proposed surgical recommendations, it is imperative that the pediatric urologist is comprehensive about the pros and cons of MIS (Table 27.1). Because most of the decades-old evidence supporting our reconstructive procedures has been established in open surgery, patients and families need to be aware of how MIS approaches can provide amazing outcome improvement opportunities and can also yield unique challenges not encountered in the original literature.

TABLE 27.1

Pros and Cons of Minimally Invasive Surgery in Children

PROS	CONS
Cosmesis Convalescence Pain control Less physiologic stress Ergonomics (robotics)	Cost Learning curve Ergonomics (laparoscopy) Specific complications (i.e., port site hernia, complications caused by pneumoperitoneum)

Advantages of Minimally Invasive Surgery

One commonly reported advantage of MIS is an improved cosmetic outcome as compared with an open approach. Laparoscopy and robotic-assisted surgery offer two distinct advantages in this regard. First, smaller laparoscopic port incisions contract over time, as compared with larger, open incisions (Finkelstein et al., 2016a, 2016b) (Fig. 27.1). Second, port placement can be adjusted to position insertion sites in less discrete locations, commonly referred to as *hidden incision endoscopic surgery* (HIdES) (Gargollo, 2011). Although many families with children undergoing urologic intervention have minimal concerns with postoperative scar appearances, scar bother can be a significant concern for patients, especially as scars grow with the patients (Garcia-Roig et al., 2017;

Wang et al., 2018). Survey data of families with children undergoing pyeloplasty, ureteral reimplantation, and bladder augmentation revealed that in all cases, laparoscopic incisions would be preferred. However, in the setting of decreased surgical efficacy, the propensity to choose laparoscopic incisions declined (Barbosa et al., 2013). Conversely, a crowd-sourced study, of which 62% of respondents had undergone previous surgery of any type, revealed a preference for dorsal lumbotomy and Pfannenstiel incisions for renal and pelvic surgeries, respectively, as compared with laparoscopic incisions. However, if told that laparoscopy would result in lower pain and improved convalescence, a significant proportion of respondents changed their preference in favor a laparoscopic approach. **Thus, it would seem that cosmesis is an important consideration for patients and families, but is prioritized lower than other surgical outcomes.**

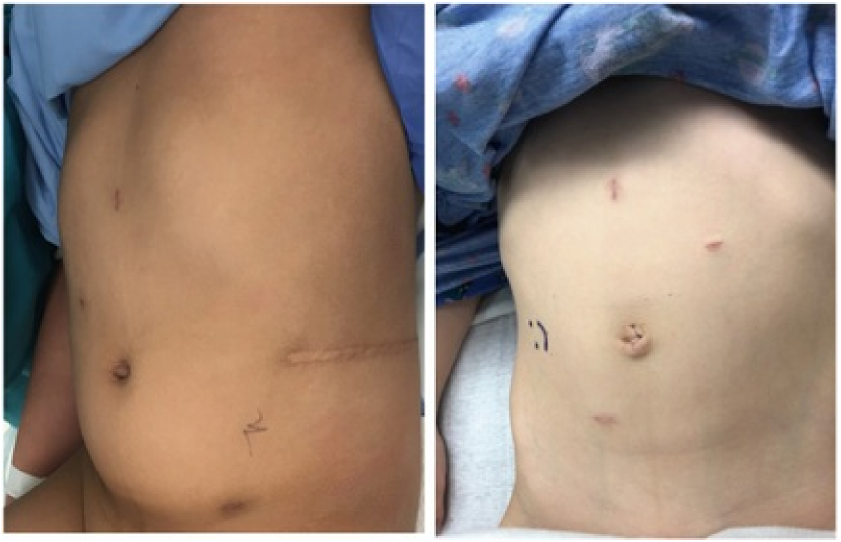

FIG. 27.1 Examples of open flank incision *(left)* and robotic port site incisions *(right)* after open and robotic-assisted pyeloplasty, respectively. The child on the left subsequently had a robotic-assisted revision pyeloplasty, and port sites are visible on the abdomen as well.

Many alterations to conventional laparoscopic or robotic port placements have been trialed to improve cosmesis. Single-port laparoscopy, or laparoendoscopic single-site surgery (LESS), has been developed primarily to reduce the need for additional incisions. The use of smaller instrumentation, allowing for correspondingly smaller incisions, has been reported in a number of urologic procedures. Mini-laparoscopy, utilizing 3- to 3.5-mm ports, has been utilized in pyeloplasty and ureteral reimplantation with equivalent success and improved cosmetic outcomes as compared with standard laparoscopic instrumentation (Fiori et al., 2013; Pini et al., 2012; Simforoosh et al., 2014). So called "needlescopic" instrumentation, utilizing endoscopic cameras and instruments 2 mm in diameter, has been reported for orchiopexy (Gill et al., 2000). Finally, micro-laparoscopic instrumentation, measuring less than 2 mm in diameter, also exists (Pini et al., 2012). Combinations of varying port sizes can further expand the efficiency of the procedure while optimizing cosmetic results.

As robotic instrumentation is not available smaller than 5 mm, additional strategies in port placement have been proposed. HIdES involves placement of the ports below the pants-line to make these incisions more discreet (Fig. 27.2). HIdES has been reported to have equivalent perioperative outcomes to standard robotic-assisted pyeloplasty (Hong et al., 2018). Typically, this involves one port within the umbilicus, and the remaining ports are placed more inferiorly. As opposed to traditional port placement, where the camera port is placed in the umbilicus, this port arrangement requires the camera to be placed in an inferior port for renal procedures, though more traditional approaches can be utilized for pelvic surgery. As such, robotic docking angles may also need to be altered to allow full functionality of all robotic arms. In a survey of families with children undergoing urologic procedures, families preferred HIdES incisions to open or standard laparoscopic or robotic incisions (Gargollo, 2011).

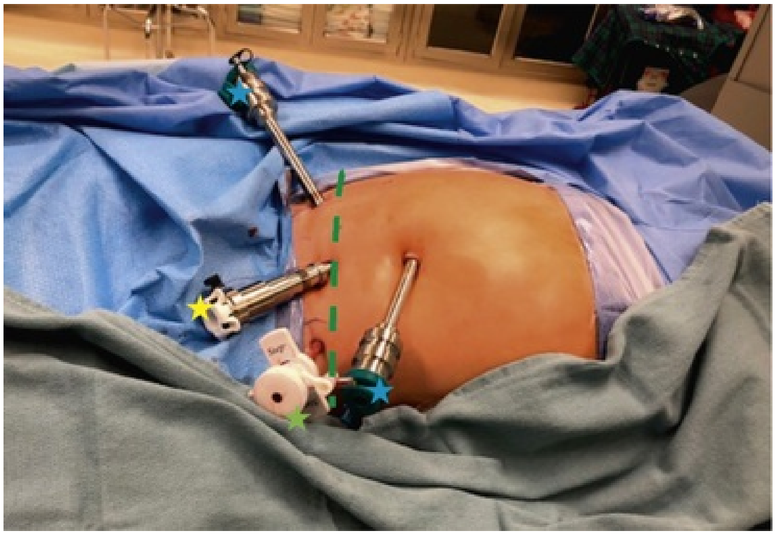

FIG. 27.2 Hidden incision port placement (HIdES) for a right robotic-assisted pyeloplasty. Placement of the robotic working port *(blue star)* in the umbilicus and the remaining robotic port *(blue star),* camera port *(yellow star),* and 5-mm assistant port *(green star)* below the pant line

(green dashed line) allow for inconspicuous incisional scars postoperatively.

Another frequently cited benefit to MIS is improved convalescence, which is a result of decreased abdominal wall stress and organ mobilization. Length of stay is frequently cited as a proxy outcome for convalescence, as little data exist regarding return to school or typical activities at home after pediatric laparoscopic or robotic interventions. In addition to reducing length of stay, another potential benefit of a minimally invasive approach would be the ability to transition traditional inpatient operations to an ambulatory setting.

Length of stay appears to be reduced in most of the common pediatric urologic interventions with either the laparoscopic or robotic approach. This has been shown to be the case in pyeloplasty on the strength of both a randomized trial and several meta-analyses of observational studies (Braga et al., 2009; Cundy et al., 2014; Gatti et al., 2017; Mei et al., 2011). Additionally, reduced length of stay is a benefit of robotic-assisted ureteral reimplant (Deng et al., 2018; Smith et al., 2011). In both procedures, the average reduction in length of stay is measured in hours, not days, as routine in-hospital care for such procedures is often relatively short. **The true benefit lies in minimizing prolonged length of stay. One recent analysis has shown an 86% decreased risk in length of stay greater than 2 days after robotic-assisted pyeloplasty** (Varda et al., 2018). In more complex operations in which a typical open operation might result in postoperative in-hospital stay of 1 week or more, the benefit of MIS appears to be even greater. In small case series for appendicovesicostomy in patients with prior abdominal operations and in augmentation enterocystoplasty, robotic-assisted approaches resulted in an average reduction in the length of stay of 2 to 2.5 days (Chua et al., 2018; Murthy et al., 2015) (Table 27.2).

TABLE 27.2

Overview of Reported Length-of-Stay Benefits for Selected Minimally Invasive Surgical Procedures in Children

OPERATION	MEAN LOS BENEFIT
Pyeloplasty (Braga et al., 2009; Mei et al., 2011)	No benefit—0.75 days
Ureteral reimplant (Smith et al., 2011)	0.75 days
Bladder augmentation/appendicovesicostomy (Murthy et al.,	2–2.5 days

2015)	

LOS, Length of stay.

Because of the cost of inpatient medicine, efforts have been made not only to reduce length of inpatient stay but to eliminate the need for overnight hospitalization altogether. Several authors have reported on the safety and feasibility of robotic-assisted upper urinary tract reconstruction as a day surgery. Although these are small, carefully selected case series, they demonstrate that these procedures, which traditionally would require at least an overnight admission, could be done in an ambulatory setting (Fichtenbaum et al., 2018; Finkelstein et al., 2016a, 2016b).

Advantages in postoperative pain control after laparoscopic or robotic-assisted procedures are challenging to measure in children, owing both to the quick recovery of most children and the challenges of comparing objective assessment tools across various age groups. Analgesic use is often measured as a proxy for postoperative pain. **Notably, intraoperative pain requirements may be higher in some pediatric urologic procedures when performed laparoscopically. The benefit of postoperative analgesia varies depending on the procedure. Procedures with minimal postoperative pain in general, such as hernia or hydrocele repair, may show limited benefit or even increased pain postoperatively with a minimally invasive approach.** This may be a result of the increased stress of the abdominal wall from pneumoperitoneum as compared with a small, less morbid inguinal incision (Koivusalo et al., 2009). However, other procedures, such as pyeloplasty and appendicovesicostomy, do show reduced postoperative analgesic requirements (Gundeti et al., 2011; Lee et al., 2006). Although some authors have reported a benefit toward reduced analgesic use after MIS approaches, improved standardization in reporting practices is needed to better quantify these outcomes.

Taken in concert, the previously mentioned data suggest that the benefit of MIS in terms of postoperative convalescence, hospital discharge, and postoperative pain experiences are likely dependent on the morbidity of the comparative open operation. For procedures in which the open approach results in minimal additional surgical stress, the benefit may not be realized and laparoscopic approaches may even be a hindrance to postoperative recovery. However, as the morbidity and complexity of the procedures increase, so too does the minimally invasive perioperative benefit to the child.

An additional benefit of a minimally invasive approach is improved visibility of vital structures. This benefit is in part a result of the optical magnification and illumination of the laparoscopic and robotic cameras (Peters et al., 2018). Direct visualization is especially useful in the deep pelvis. The benefits of improved visualization include decreased manipulation of the posterior bladder wall during robotic-assisted ureteral reimplantation (▶Video 27.1), improved visualization of the distal ureter during ureterectomy (▶Video 27.2), and improved visualization of the spermatic vessels tracking superiorly through the retroperitoneum during laparoscopic orchiopexy (Boysen et al., 2016; Ellison and Lendvay, 2017).

Drawbacks of Minimally Invasive Surgery

There exist three major detractors to MIS in pediatrics. **First, laparoscopic and robotic-assisted techniques are often complicated and technically demanding, necessitating a steep learning curve. Second, MIS may be ergonomically more stressful to the surgeon, especially with regard to pure laparoscopy. Third, the addition of the robotic platform may significantly increase procedural costs.**

Learning curves for laparoscopic and robotic procedures, specifically pyeloplasty and ureteral reimplantation, have been estimated to be between 20 and 40 cases to achieve equivalent outcomes to open procedures (Akhavan et al., 2014; Sorensen et al., 2011; Tasian et al., 2013). Although a full discussion of surgical training in MIS will be discussed later in this chapter, it should be noted that such studies were performed in the earlier era of robotic-assisted surgery. As surgeons become exposed earlier and more often to robotic-assisted procedures throughout surgical training, learning curves early in practice may actually decrease over time.

The ergonomic stress of laparoscopy cannot be understated. Surgeons demonstrate increased physical and mental strain while performing laparoscopic tasks, such as suturing, as compared with the same tasks in an open setting (Berguer et al., 2001). As in open surgery, high-volume laparoscopic surgeons may experience significant or even debilitating injuries from challenging ergonomic conditions during laparoscopy. Indeed, up to 87% of surgeons in one survey reported physical pain associated with laparoscopic experience (Park et al., 2010). The robotic platform may provide improved ergonomics and lower physical strain experienced by surgeons (Berguer and Smith, 2006). However, it is important to note that up to 56% of high-volume surgeons will experience evidence of ergonomic strain, even with the robotic platform (Lee et al., 2017).

Cost is perhaps the largest detractor for MIS, especially as it pertains to robotics, wherein the initial robotic setup costs typically run between $1 and $2 million, and maintenance costs are greater than those for standard laparoscopic equipment (Barbash and Glied, 2010). Thus, additional costs per case for robotic-assisted surgery typically runs between $1000 and $4000 as has been shown in several cost-comparison studies for common pediatric procedures such as pyeloplasty and ureteral reimplantation (Bennett et al., 2017; Kurtz et al., 2016; Varda et al., 2018). Because of a reduced length of stay for robotic procedures, direct costs per robotic procedure may actually be lower than the comparative open surgery (Rowe et al., 2012). However, because of overhead and potential increase in operating room (OR) time, these benefits may not translate into overall cost savings (Bennett et al., 2017; Varda et al., 2018). Thus, benefit in overall cost is likely volume dependent as a result of large equipment overhead costs, and may only be realized if a reduced length of stay creates a greater capacity for the hospital to improve patient throughput (Leddy et al., 2010).

In summary, the benefits of minimally invasive pediatric urology are real and measurable. Barring disruptive technology to place downward pricing pressure on the dominant robotic companies, cost-reduction in robotic surgery will likely be dependent on efficient use of operative time and minimizing postoperative costs. Relying on the value-equation in health care, where value is equal to quality divided by cost, one must demonstrate a *value* in MIS. Primary outcomes in terms of surgical success rates are not likely to be improved upon from an open approach, where success rates for ureteral reimplant and pyeloplasty already reach greater than 95%. Thus, it is incumbent on minimally invasive pediatric urologists to demonstrate consistently reproducible secondary benefits such as improved convalescence and decreased hospital stay and to further quantify the outpatient benefits in terms of quality of life and patient-reported outcomes for MIS while reducing the cost discrepancies to the open approach.

Key Points: Advantages and Disadvantages of Minimally Invasive Surgery

- Patient preferences for postsurgical incisions are influenced by location; innovative port placements optimize cosmesis without compromising outcomes.
- Mean length-of-stay reduction with MIS may be minimal, but benefits are

realized by limiting prolonged stays and enabling more ambulatory surgical procedures.

- Although robotics may offer ergonomic advantages over laparoscopy or open surgery, ergonomic fatigue is commonly reported with use of the robotic platform as well.

Physiology of the Pneumoperitoneum

Unlike open surgery where the abdominal cavity experiences ambient temperatures and atmospheric pressures, MIS approaches introduce unique physiologic changes, which can alter the normal expectations of perioperative and postoperative course. Familiarizing oneself with these considerations is critical to minimizing cardiovascular, pulmonary, intracranial, renal, and stress-response–related morbidity.

Cardiovascular Changes

Cardiovascular changes during laparoscopy may be seen because of the impact of the pneumoperitoneum on vascular resistance, the sympathetic and parasympathetic responses to peritoneal distension, or the response to systemic intravascular absorption of carbon dioxide (CO_2). Initial insufflation will stimulate the vagal nerve, which can rarely result in cardiovascular collapse but is more typically self-limited (Aghamohammadi et al., 2009; Myles, 1991). Tachyarrhythmias might arise from sympathetic responses to the distended peritoneum or hypercapnia from absorption of the insufflated CO_2. These tachyarrhythmias are typically limited in duration and do not appear to affect overall mean heart rates or arterial blood pressure (Bozkurt et al., 1999). In older children or with intra-abdominal pressures greater than 10 mmHg, a decrease in cardiac index may be observed (De Waal and Kalkman, 2003). This decrease in cardiac index may be the product of compression of the right atrium and subsequent decrease in venous return (Gueugniaud et al., 1998). **Even insufflation at less than 10 mmHg can result in significant changes to cardiac preload and afterload, as measured by transesophageal echocardiography. These changes do not correlate to measurable changes in cardiac performance, such as left ventricular ejection fraction, perhaps a result of increased workload on the myocardium** (Gentili et al., 2000). Conversely, operating at lower insufflation pressures of 5 mmHg results in an increase in cardiac index and may be of importance in children with congenital cardiac disease (De Waal and Kalkman, 2003).

Pulmonary Changes

Insufflation of the abdominal cavity results in substantial changes to intraoperative pulmonary function. These observed changes are thought to be the result of a number of factors, including upward displacement of the diaphragm, reduction in muscular tone of the chest wall, and decreased venous return and subsequent intrathoracic blood volume caused by increased abdominal pressures (Manner et al., 1998). These effects may be further compounded by steep Trendelenburg positioning required in pelvic surgery. Infants may be particularly affected by pulmonary stress because of their small size. **Younger children absorb more CO_2 during abdominal insufflation as a proportion of their body mass, which may lead to prolonged effects of CO_2 elimination in the immediate postoperative period** (McHoney et al., 2003)**. During laparoscopic procedures utilizing up to 15 mmHg of insufflation pressure, tidal volume and dynamic compliance decrease.** Proportionally, the most substantial changes are noted in the pulmonary dynamic compliance, which had been measured to decrease in infants by a mean of 48% from baseline. Trendelenburg positioning tends to increase peak inspiratory pressures while decreasing lung compliance during laparoscopy. To counteract these changes, ventilator adjustments are required to restore end-tidal CO_2 to baseline, including increases in peak inspiratory pressure or ventilator rate (Bannister et al., 2003; Taylor et al., 2006). Similar pulmonary effects are seen with both transperitoneal and retroperitoneal approaches, although retroperitoneal insufflation has not been studied as extensively (Halachmi et al., 2003). CO_2 absorption will result in rise in both the $PaCO_2$ and end-tidal CO_2. End-tidal measurements appear to rise more dramatically in some instances, such as in children with complex cardiac anatomy. Furthermore, CO_2 continues to be eliminated up to 10 minutes after desufflation of the abdomen. As such, in children most susceptible to changes in the pulmonary dynamics, direct measurement of $PaCO_2$ via arterial blood draw may be preferred (Wulkan and Vasudevan, 2001).

Intracranial Pressure

A significant rise in intracranial pressure has been noted during pediatric laparoscopy. This is of particular importance in children with ventriculoperitoneal (VP) shunts. Hypercapnia, which results in part from changes in pulmonary gas exchange and direct absorption of CO_2 from the peritoneum (Gargollo, 2011), will increase cerebral blood flow (Wedgewood and

Doyle, 2001). Interestingly, even when arterial CO_2 levels are kept constant, an increase in intracranial blood flow during pneumoperitoneum still occurs. The mechanism by which the intracranial blood flow increases in the absence of hypercapnia is unclear but is hypothesized to be either caused by direct redistribution of cardiac output or catecholamine-driven vasoconstriction (Huettemann et al., 2002). **Intracranial pressure increases substantially during laparoscopy in children with VP shunts, thought to be in part a result of increased venous congestion via a "Valsalva-like" mechanism and a direct obstruction to the distal shunt itself.** This rise in pressure has been successfully managed with ventricular drainage (Uzzo et al., 1997). However, the use of invasive monitoring for intracranial pressures in these children has been called into question. In spite of prolonged operative times and insufflation pressures of up to 20 mmHg, one series of children with VP shunts found no changes in clinically significant parameters, such as bradycardia or hypertension, associated with pneumoperitoneum. Furthermore, shunt revision rates were similar to that reported elsewhere in the literature, suggesting laparoscopic procedures can be safely performed in this patient population without invasive monitoring (Jackman et al., 2000).

Renal Physiology

Oliguria and anuria during laparoscopic surgery is a known phenomenon of particular note during urologic surgeries. This effect appears more profound in younger children, with up to 88% of infants younger than 1 year of age exhibiting short periods of intraoperative anuria. Although only 14% of children older than 1 year of age will exhibit anuria, up to one-third of those younger than 1 year of age will exhibit oliguria (Dammeier et al., 2005). These changes are thought to arise from decreased renal blood flow, which results from decreased cardiac output, impaired venous return, and direct compression of the pneumoperitoneum on the kidney. Interestingly, there does appear to be intrarenal shunting of blood flow, resulting in preferential increases in blood flow during pneumoperitoneum to the renal medulla (Razvi et al., 1996). Direct compression has been postulated to be the most important component of decreased renal blood flow, based on in vivo animal models, as changes in the venous return and cardiac output appear to have minimal impact on renal perfusion (Chiu et al., 1994; Razvi et al., 1996). However, declines in glomerular filtration rate and release of renal injury markers, such as *N*-methyl-ß-D-glucosaminidase, occur well after release of pneumoperitoneum, suggesting a role for renal regulatory mechanisms beyond just compression (Cisek et al., 1998). Notably, all of these changes do appear to be reversible, with clinical parameters normalizing within 24 hours and physiologically measured parameters normalizing within 1 week (Cisek et al., 1998; Dammeier et al., 2005). However, early in recovery, the physiologic impact on renal function remains abnormal within the first 60 to 90 minutes postoperatively (Cisek et al., 1998; Razvi et al., 1996). From a clinical standpoint, it is important to recognize oliguria as a potential outcome after laparoscopy unrelated to intravascular fluid status. As this effect will normalize spontaneously and in the absence of other markers of under-resuscitation, isolated postlaparoscopic oliguria should not be managed with bolus-hydration beyond typical postoperative management. However, because renal blood flow and function may be affected in the early postoperative period, caution should be used during this timeframe in administration of medications such as non-steroidal anti-inflammatory drugs and aminoglycoside medications that may further alter renal blood flow.

Acid-base physiology may be significantly altered by CO_2 absorption during insufflation. Hypercapnia is likely driven by two main effects. At insufflation pressures less than 10 mmHg, direct absorption of the gas by the peritoneal lining results in elevated $PaCO_2$. Once intra-abdominal pressures exceed 10 mmHg, increased respiratory dead space from ventilation-perfusion mismatch likely also contributes to a rise in $PaCO_2$ (Lister et al., 1994). Acidosis resulting from an increase in $PaCO_2$, however, returns to baseline after desufflation. This is in contrast with lactic acidosis noted after laparotomy, which persists for several hours postoperatively (Kwak et al., 2010). However, in vivo models to replicate pneumoperitoneum in infants suggest that smaller peritoneal spaces may be more susceptible to acid-base changes, resulting in more profound and persistent changes to base excess lasting several hours after surgery (Sümpelmann et al., 2006). Porcine studies suggest that maintenance of intravascular volume with colloid replacement during laparoscopy can mitigate hemodynamic changes and base-excess, though the implications of this approach in clinical practice remain undefined (Osthaus et al., 2008). In addition to systemic changes in CO_2 concentration, local increases in CO_2 within the peritoneal cavity result in a buildup of H^+ and HCO_3^-. This local acidosis is thought to contribute to postlaparoscopic pain (Hanly et al., 2005).

Stress Response to the Pneumoperitoneum

Increase in intra-abdominal pressure has been associated with several systemic stress responses, including catecholamine and cytokine release. Pneumoperitoneum results in release of epinephrine and norepinephrine within 5 minutes of insufflation, with a more profound response in the lateral decubitus position (Mikami et al., 1996). At 20 mmHg of intra-abdominal pressure, the release in catecholamines appears to be associated with and is likely driven by decreased cardiac output and increased systemic vascular resistance. Stimulation of the sympathetic nervous system was not noted at lower intra-abdominal pressures of 10 mmHg, suggesting a modifiable effect of pneumoperitoneum and potential benefit to maintaining lower insufflation pressures during laparoscopy if feasible (Mikami et al., 1998).

The stress response after laparotomy can be significant, but less so after laparoscopy because of the ability to minimize tissue damage and visceral manipulation. **Interleukin-6 and C-reactive protein levels remain significantly elevated after open surgery as compared with laparoscopic intervention for up to 48 hours. Pain and fatigue scores are correspondingly lower after laparoscopy** (Jakeways et al., 1994; Kristiansson et al., 1999). The benefits of laparoscopy on inflammatory responses appear to be realized both in local (i.e., peritoneal) inflammatory markers and systemic inflammatory assessment. Counts of polymorphonuclear cells and macrophages, as well as interleukin-6 release, were lower on peritoneal lavage after CO_2 laparoscopy than laparotomy. Interestingly, achieving pneumoperitoneum with room air, as opposed to CO_2, resulted in a similarly increased inflammatory response as laparotomy, suggesting that at least some of the benefit of the minimized laparoscopic stress response is a result of the characteristics of the insufflation gas (Ure et al., 2002). The dampened local immune response has been proposed to be the result of CO_2 conversion to H^+ and HCO_3^-, resulting in peritoneal acidosis (Hanly et al., 2005). This dampened response has been shown to blunt the inflammatory cascade associated with sepsis (Hanly et al., 2003; Hiki et al., 2006). Of note, pediatric-specific data has not shown such changes in the inflammatory response postlaparoscopy, suggesting that these changes may be age-dependent (Bozkurt et al., 2000; McHoney et al., 2005; Simon et al., 2009).

Key Points: Physiology of the Pneumoperitoneum

- Infants pose anatomic and physiologic challenges such as limited working space, a pliable abdominal wall, and cardiopulmonary changes with insufflation.
- Insufflation pressures even less than 10 mmHg may affect cardiac preload and afterload, with specific implications in children with complex cardiac anatomy.
- A diminished postoperative inflammatory response may result in postoperative complications such as visceral injury presenting without peritoneal signs.
- Intracranial pressure may increase with pneumoperitoneum, though the presence of ventriculopertioneal shunts is not a contraindication to laparoscopy.
- Oliguria after laparoscopy is common and should not be managed with reflex fluid resuscitation without further assessment of volume status.

Patient Selection for Mimimally Invasive Surgery

Although MIS is a highly technical approach to surgery, decision making and judgment determine significant outcomes in our patients. Understanding when to apply and not to apply MIS approaches is vital to optimizing surgical success. The most common pediatric procedures undertaken in a minimally invasive fashion are orchiopexy for intra-abdominal testicles, pyeloplasty, and ureteral reimplantation (▶Video 27.3). However, a number of successful MIS applications have been described, as listed in Table 27.3.

TABLE 27.3

Minimally Invasive Pediatric Urologic Procedures Reported in the Literature

UPPER URINARY TRACT
Radical nephrectomy (Hamilton et al., 2000; Yao and Poppas, 2000)
Partial nephrectomy (Yao and Poppas, 2000; Lee et al., 2005)
Nephroureterectomy (Figenshau et al., 1994; Yao and Poppas, 2000)
Heminephroureterectomy (Janetschek et al., 1997; Yao and Poppas, 2000)
Pyeloplasty (Lee et al., 2006; Minnillo et al., 2011)
Calyceal diverticulectomy (Casale et al., 2004a, 2004b, 2004c; Long et al., 2015)
Ureterocalicostomy (Casale et al., 2008a, 2008b, 2008c; Radford et al., 2011)
Pyelolithotomy (Casale et al., 2004a, 2004b, 2004c; Lee et al., 2007)
Nephropexy (Resnick et al., 2006; Matsui et al., 2004)
Renal cyst ablation (Okeke et al., 2003; Shiraishi et al., 2006)
Renal denervation (Resnick et al., 2006; Casale et al., 2008a, 2008b, 2008c)
Adrenalectomy (Miller et al., 2002; Skarsgard and Albanese, 2005)
LOWER URINARY TRACT
Bladder diverticulectomy (Kok et al., 2000; Meeks et al., 2009)
Partial cystectomy and removal of urachal remnant (Yamzon et al., 2008; Jeong et al., 2013)
Appendicovesicostomy (Casale et al., 2004a, 2004b, 2004c; Nguyen et al., 2009)
Auto-augmentation (Ehrlich and Gershman, 1993; Poppas et al., 1996)
Intravesical and extravesical ureteral reimplant (Kutikov et al., 2006b; Casale et al., 2008a, 2008b, 2008c)

Ureteroureterostomy (Leavitt et al., 2012; Ellison and Lendvay, 2017)
Augmentation enterocystoplasty (Gundeti et al., 2011; Murthy et al., 2015)
Utricle excision (Yeung et al., 2001; Lima et al., 2004)

GENITAL SURGERY

Varicocelectomy (Glassberg et al., 2008; Kaouk and Palmer, 2008)
Neovagina (Templeman et al., 2000; Kim et al., 2011)
Undescended testis (Jordan et al., 1992; Godbole and Najmaldin, 2001)
Sacrocolpopexy (Christopoulos et al., 2011; Henninger et al., 2015)
Retroperitoneal lymph node dissection (Tomaszewski et al., 2010; Cost et al., 2012)

OTHER

Antegrade continent enema (Van Savage and Yohannes, 2000; Karpman et al., 2002)

Although several patient factors make MIS more technically challenging, there are currently only two absolute contraindications to laparoscopic and robotic-assisted surgery in children: (1) inability of the patient to tolerate pneumoperitoneum and (2) inability of the surgeon to safely perform the procedure.

The ability of a child to tolerate pneumoperitoneum is dependent on adequate cardiac and pulmonary reserve in response to the increased intra-abdominal pressure. The degree of stress on the cardiopulmonary circulation is dependent on the level of pneumoperitoneum. Thus, children with more severe cardiopulmonary disease can be managed safely by operating at lower insufflation pressures of 5 mmHg, which results in a subsequent increase in cardiac index (De Waal and Kalkman, 2003). Even in severe cardiopulmonary disease, laparoscopy has been safely performed. **However, as children with congenital cardiac disease have higher 30-day morbidity and mortality, this unique patient population requires special considerations during laparoscopy** (Chu et al., 2017).

Although there are no specific age or size restrictions in laparoscopy or robotic-assisted surgery, several considerations must be made in preparing to operate on the youngest of children. Robotic-assisted surgery has been reported in children within the first week of life, as small as 2.2 kg (Mariano et al., 2004; Meehan, 2009; Meehan and Sandler, 2007). Several reports have demonstrated the safety of common pediatric urologic procedures (e.g., pyeloplasty) in children younger than 1 year of age, using both pure laparoscopic and robotic-assisted techniques (Kutikov et al., 2006a, 2006c). Furthermore, laparoscopic orchiopexy in infants with nonpalpable testes has arguably become a standard of care, considered equal to open exploration in experienced hands (Kolon et al., 2014). Even retroperitoneal surgery, with a smaller relative working space than transperitoneal access, has been successfully reported in infants (Leclair et al., 2009). **However, one must consider that the working space of the infant will be limited, often allowing only 1 L of insufflation volume as compared with 5 to 6 L of insufflation in the adult population** (Finkelstein et al., 2015)**. Smaller working spaces can pose technical challenges to the surgeon, making intra-corporeal suturing and multiquadrant surgery more difficult.** The degree to which this smaller working space affects perioperative outcomes or operative time has not been well quantified. However, when measuring the distance between the anterior superior iliac spines and also the puboxyphoid distance, distances less than 13 cm and 15 cm, respectively, appear to be associated with higher rates of arm collision during robotic surgery. Percutaneous introduction of 3-F graspers, 2-mm scissors, or antegrade ureteral stent introduction via a 14-gauge angiocatheter needle can eliminate the need for additional 3- or 5-mm assistant ports and thus allow for additional extracorporeal working space for the surgeon and assistant (Hotaling et al., 2009; Noh et al., 2011). Lastly, the relatively small size of an infant compared with the large footprint of the robotic-platform itself can limit nursing and anesthesia access to the child. Thus, proper perioperative planning is required to ensure safe and efficient patient positioning and access to pressure points, intravenous catheters, and the airway for the entire operative team (Mariano et al., 2004). In closing, although feasible, robotic and laparoscopic surgery in younger infants may pose additional technical challenges.

Operating on a hostile abdomen with higher risk for intra-abdominal adhesions because of prior abdominal surgeries or procedures such as VP shunts is often considered a relative contraindication to minimally invasive surgery. **Laparoscopy in children with prior abdominal surgeries is associated with a higher rate of open conversion and intraoperative events such as enterotomy** (Metzelder et al., 2006)**. However, successful completion of these procedures in a laparoscopic fashion is feasible, and when accomplished, may yield increasing returns in terms of convalescence and pain control** (Chua et al., 2018). Because not all reoperative abdomens are similar, predicting *a priori* children that may be at higher risk can be challenging. A “Hostile Abdomen Index” has been reported, with scores ranging from 1 to 4 given for both preoperative conditions and intraoperative findings. A preoperative score of

3 or 4 has been associated with a higher risk for significant hemorrhage and enterotomy and may be useful to help guide surgeons in preoperative counseling and perioperative planning (Goldfarb et al., 2014) (Table 27.4).

TABLE 27.4

Hostile Abdomen Index Scoring Table

1 No prior surgery No hernia No skin disease or infection	**2** One prior laparotomy or hernia
3 Two prior laparotomies Extremes in patient size (small or large) Coagulopathy Prior abdominal radiation (not at surgical site) History of inflammatory bowel disease Acute abdominal wall infection (not at surgical site)	**4** More than two laparotomies History of diffuse peritonitis or abdominal abscess Large abdominal mass Abdominal mesh Bowel obstruction with severe distension Prior failure of laparoscopy caused by adhesions Prior abdominal radiation (intended surgical site) Active inflammatory bowel disease Hemodynamic instability Severe chronic obstructive pulmonary disease Late pregnancy Acute abdominal wall infection (at port site)

Key Points: Patient Selection in Minimally Invasive Surgery

- The inability to safely achieve pneumopertioneum is the only patient factor that contraindicates MIS.
- Patient positioning for infants must take into account the ability of the anesthetic team to reach the patient's airway and intravenous access.

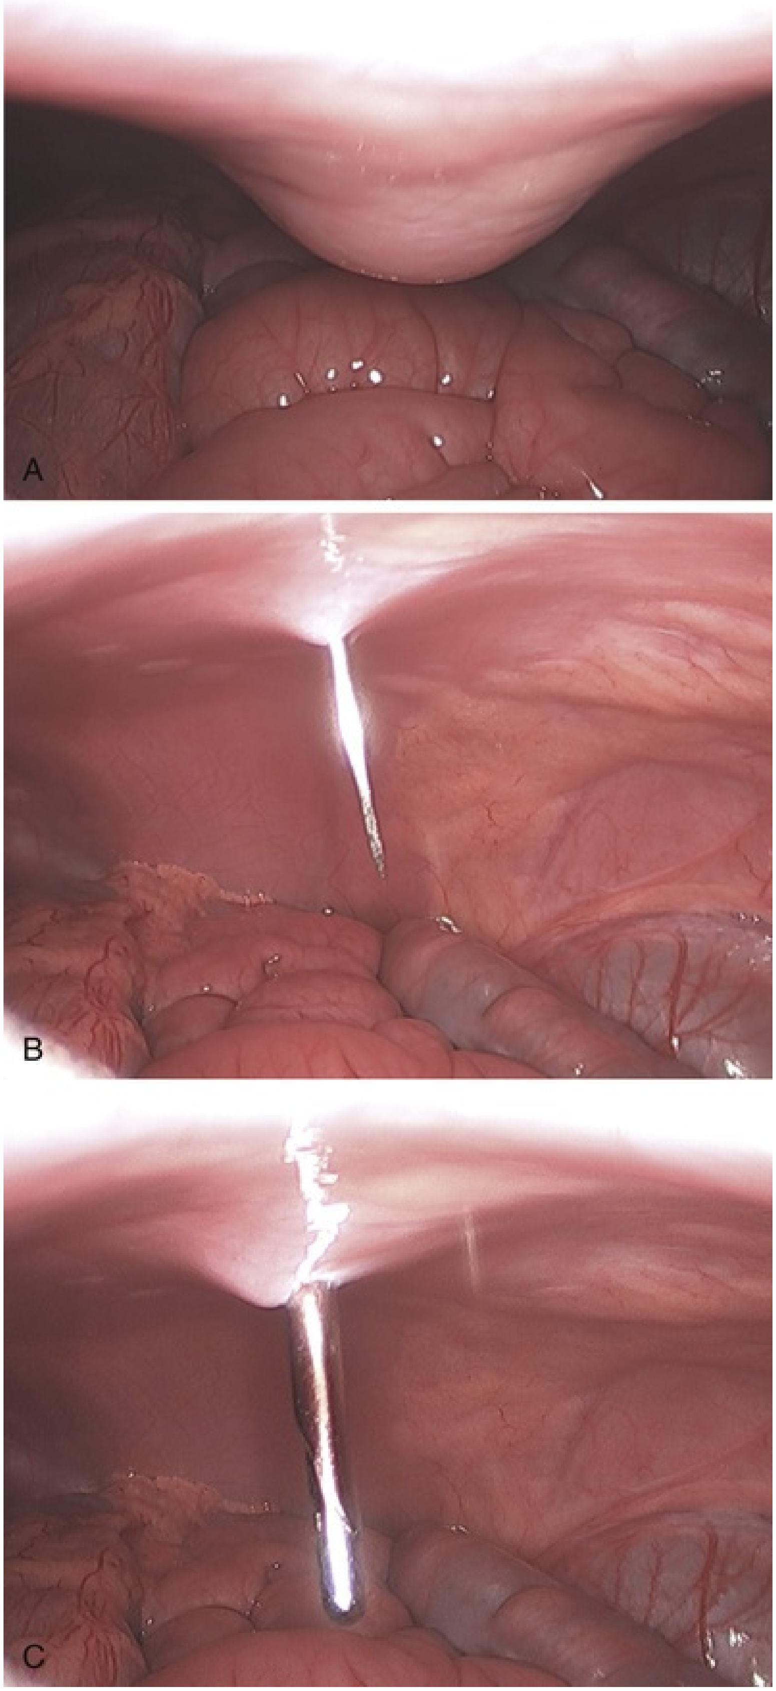
- Preoperative assessment of a hostile abdomen will suggest risk for conversion to open surgery, aid in surgical planning, and contribute to patient counseling.

Access

As in adult MIS approaches, access or introduction of the initial ports can be varied depending on surgeon preference, anatomic considerations, and equipment availability.

Veress Needle

The Veress needle operates on a principle of a covered needle, exposed during applications of pressure and retracting on release of this pressure. Insertion of the needle through the fascial planes will expose the needle at the point of pressure against the fascia and retract once the fascia has been perforated, thus covering the needle when it enters the abdomen. Because of the laxity and thin nature of the pediatric abdominal wall, **Veress insertion presents several challenges. First, it may be difficult to create enough tension to release the needle and perforate the fascia, even with excessive force (Fig. 27.3). Second, one must be wary of the depth of insertion, as the vasculature and viscera may reside shallower than anticipated in older patients.** Age younger than 2 years has previously been described as a relative contraindication to Veress needle access (Schulam et al., 1999).



A
B
C

FIG. 27.3 Veress needle for laparoscopic access. (A) Percutaneous attempt at Veress placement in an infant, viewed intra-abdominally. Note the laxity of the abdominal wall, which is displaced and near the underlying small intestine; (B) incising the fascia and peritoneum in the same infant with an 11-blade scalpel to allow easier entry; (C) insertion of the Veress needle after incision of the fascia. In this approach, the sharp edge of the Veress needle is not exposed, but the Veress may still serve as a guide for insertion of a 5-mm radially dilating port.

Several facets of Veress access are commonly debated, such as point of entry and the need to lift the abdominal wall before insertion. Traditionally, midline insertion of the Veress needle at the umbilicus was preferred (Vilos et al., 2007). However, it should be noted that the umbilicus is a poor indicator for the location of the aortic and caval bifurcations, and thus any blind insertion techniques at the midline should be approached with caution (Sriprasad et al., 2006). Palmer's point, located within the left upper quadrant 3 cm inferior to the left subcostal border in the midclavicular line, is an alternative point of entry when there is a risk for periumbilical adhesions or unsuccessful umbilical access (Vilos et al., 2007). **Lifting the abdomen by hand or with towel clips does not appear to raise the peritoneal lining above the underlying viscera sufficiently enough to prevent injury** (Vilos et al., 2007)**. Furthermore, such an approach appears to have a higher risk for failed access and failing to prevent complications** (Ahmad et al., 2008).

Complications of Veress needle access include major vascular or visceral injury, failed access, extraperitoneal insufflation, or minor vascular injury. Overall, complication rates are low, with rates of only about 0.2% presented in the literature. Furthermore, rates of vascular and visceral injury compose a minority of these complications. However, the majority of visceral injuries are considered “major” (Azevedo et al., 2009). Interestingly, self-reported complications via a survey of members of the Society of Pediatric Urology revealed a higher reported rate of Veress needle injuries than open access injuries, although this was relatively early in the widespread use of laparoscopy. The overall rate of access complications was higher than found in other published literature, suggesting a potential for publication bias in assessing these rare injuries (Peters, 1996). Although the rates of complications are low, the consequences of Veress injury may be substantial. During passage of the Veress needle, several tests may be employed to test for adequate intra-abdominal placement. These include a double-click test, aspiration, hanging drop test, and measurement of initial insufflation pressures. The double-click test is based on the theory that one is perforating two fascial layers during insertion. Aspiration is performed with a small syringe to confirm no return of blood or visceral contents. The drop test involves instillation of saline via the needle, where prompt drainage of the saline could indicate peritoneal access. Although these three tests, particularly the aspiration test, may help to ensure no vascular or visceral injury exists, they have a low positive predictive value to suggest appropriate peritoneal placement. However, consistent measurements of initial insufflation pressures less than 10 mmHg are highly predictive of adequate peritoneal access (Teoh et al., 2005). The true benefit of many of these confirmatory tests may lie in the early recognition of major intra-abdominal injury, where proceeding with insufflation and dilation of the trocar could lead to catastrophic consequences.

Open Access

Open laparoscopy, or the Hasson technique, was first described in 1970 and relies on a small incision with access into the peritoneum to allow for direct insertion of a laparoscopic port. This technique is classically performed with an incision at the umbilicus with exposure and incision of the abdominal fascia. Visualization of the bowel or omentum is considered an essential step in confirming safe intra-abdominal access (Hasson et al., 2000). A modification of this technique involves direct entry through the umbilicus, where there is a natural absence of the transabdominal fascial planes (Fig. 27.4). The transumbilical approach has been shown to be safe and efficient, often taking less than 1 minute. This technique relies on a small incision, equal to or less than the port diameter, to prevent leakage of pneumoperitoneum from the opening (Esposito, 1997; Nakaoka et al., 2010). Even in obese patients, in whom the technique might be more challenging, efficiency is not lost in the majority of cases (Moberg et al., 2007). Consideration of the umbilical anatomy is important for this technique. Even in adults, up to 25% of the population may have a natural fascial opening at the umbilicus, based on cadaver studies (Fathi et al., 2012). However, the umbilicus is typically covered with thickened skin and a confluence of the medial and median umbilical ligaments with the ligamentum teres hepatis. Variations exist in the configuration and branching of these ligamentous structures, which could affect ease of umbilical access (Oh et al., 2008). **Of clinical relevance, it is important to note that confluence of these ligaments at the umbilicus may make access more challenging, potentially**

necessitating a more formal exposure and incision of the umbilical stalk (Tröbs et al., 2016)**. Because support of the umbilical opening varies as well, it is important to formally close the fascial edges to prevent port site hernia after the procedure** (Tröbs et al., 2016).

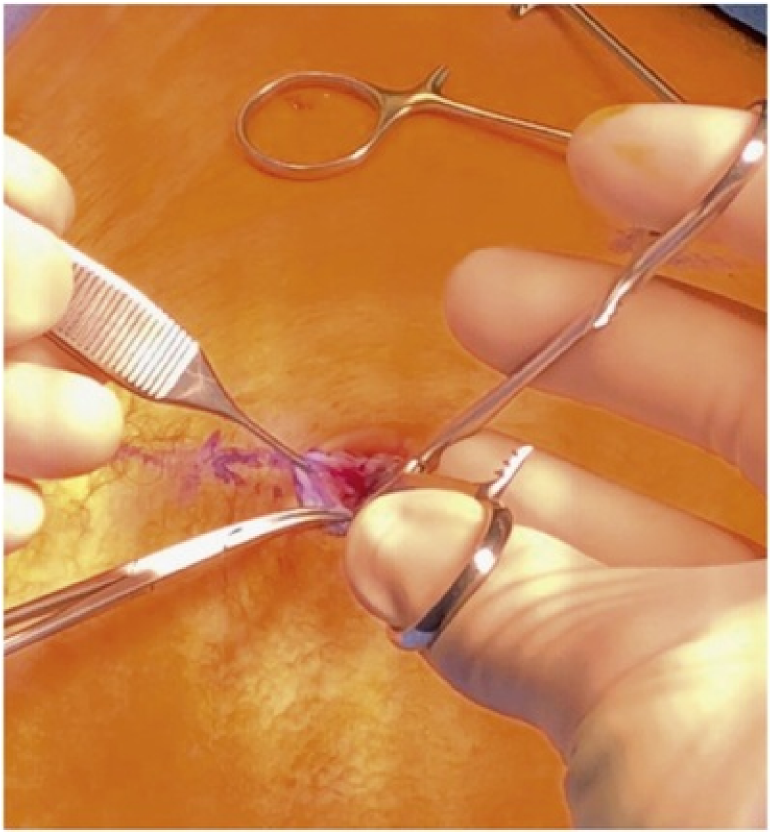


FIG. 27.4 Open umbilical access. The surgeon retracts the inferior umbilical edge with Adson forceps while the assistant retracts laterally. The hemostat is introduced gently inferiorly through the natural fascial opening into the peritoneum.

Visual Obturator Access

Optical access trocars allow direct visualization with the laparoscopic camera while the port is being placed into the abdomen. The surgeon can thus visualize the layers of the abdominal wall as they are entered. Successful uses of these devices have been described with and without prior insufflation via a Veress needle and may be more effective than the Veress needle in accomplishing successful access (Marcovich et al., 2000; Rabl et al., 2008). The optical access trocar does not eliminate risk for major vascular or visceral injury, although the rates of injury are quite low, similar to other access techniques (Sharp et al., 2002; String et al., 2001). Rates of injury may be higher in the desufflated abdomen and some surgeons prefer to gain Veress needle access with pneumoperitoneum before placement of the visual obturator (Brown et al., 2005). One limitation of the visual obturator in children is the size of most devices, ranging between 10 and 12 mm (Brown et al., 2005; McKernan and Finley, 2002).

Comparative Effectiveness of Access Techniques

Numerous studies have assessed comparative success and risks with various access techniques, though most of the comparisons are between direct access (i.e., Hasson) and Veress needle access. Commonly, outcomes are stratified by major complications such as visceral or major vascular injuries, minor complications such as omental injury or insufflation into an undesired space (i.e., pre-peritoneal), and failure of access. **There does not appear to be any significant difference in the incidence of visceral injury between open and Veress needle access techniques, though the incidence rates are so low that demonstrating statistical differences would require an enormous study population** (Jiang et al., 2012). Minor complications such as preperitoneal insufflation do appear to be higher with the Veress needle technique. Furthermore, failure of access appears to be lower with direct open entry (Ahmad et al., 2008; Merlin et al., 2003). One randomized trial evaluating direct open access to a visual obturator technique found a quicker time to entry with direct access at a cost of potential higher risk for access-related complications, including one case requiring open conversion. However, given the small number of patients enrolled, it is difficult to generate a final conclusion on overall complication rates (Minervini et al., 2008). It is important to note that none of these studies included pediatric patients, so direct prospective comparisons of any access technique in children are lacking.

Key Points: Access

- When placing a Veress needle in children, considering the laxity and thin nature of the abdominal wall helps minimize intra-abdominal vascular or visceral injury.

- Veress needle access has a higher rate of failed access but similar rates of major complications; however, studies specific to children are lacking.
- The umbilicus is a poor predictor of the location of the aortic bifurcation, which may exist superior to the umbilicus in a substantial proportion of patients.

Approach

Transperitoneal

The most common approach to laparoscopic procedure is via the peritoneum, which has the advantage of easy access to the abdomen, a large working space, and surgeon familiarity with anatomic orientations. Although the pediatric abdomen distends to a smaller absolute volume than the adult abdomen, the laxity of the pediatric abdominal wall likely allows for greater proportional volume expansion than in the adult patient. Transperitoneal approaches are preferred for intra-abdominal testes, which can be easily identified typically at the level of or just above the internal inguinal ring. Renal surgery can be approached via a transperitoneal approach with reflection of the colon or (on the left side) transmesenteric exposure. The posterior bladder is easily accessible via a transperitoneal approach and can be routinely mobilized to expose the prevesicular space if needed. Furthermore, the intestinal tract is easily accessible for any reconstruction that might require bowel.

Retroperitoneal

The retroperitoneal approach is favored by some surgeons, although it may be technically challenging, resulting in a smaller working space and anatomic orientation that may not be as intuitive to the early learner. However, this approach avoids the peritoneal cavity and its contents, thereby potentially reducing the risk for catastrophic complications such as visceral injury. Renal surgery is especially attractive via this approach, and all common pediatric renal operations including nephrectomy, heminephrectomy, and pyeloplasty have been described in a retroperitoneal manner (El-Ghoneimi et al., 2000, 2003; Wallis et al., 2006). Similar to a retroperitoneal approach, the space of Retzius can also be insufflated and accessed without entering the peritoneum. Although this technique is utilized in adult prostatectomy, applications in the pediatric population may be more limited, though the anterior bladder neck could be well visualized via this approach.

Vesicoscopic

In management of the lower urinary tract, specifically ureteroneocystotomy, minimally invasive approaches with access directly into the bladder have been described. Similar in the challenges to retroperitoneal surgery, this approach is limited by smaller working space. Complications may occur at a higher frequency in small bladders (Kutikov et al., 2006b). Furthermore, although the ports may be visualized with direct insertion into the bladder, any extravesical tracking is not visualized, which may place intra-peritoneal structures at risk during port placement. These procedures have been described using pure laparoscopy and robotic assistance (Peters and Woo, 2005). Although the learning curves have not been strictly studied in these populations, there appears to be higher rates of complications and failures in the early (i.e., 30 cases) surgical experience (Jayanthi, 2018; Kutikov et al., 2006b). In experienced hands, however, the success rate approaches that of open repair after reaching the learning curve (Jayanthi, 2018).

Key Point: Approach

- Retroperitoneal and vesicoscopic approaches minimize exposure to the peritoneal cavity but may pose challenges related to small working spaces.

Equipment and Instrumentation

Knowledge of all available instrumentation in one's armamentarium is vital to being a safe and efficient minimally invasive surgeon. This includes knowledge of standard and advanced laparoscopic and robotic instruments, options for hemostasis, and optimal imaging strategies.

Laparoscopic Ports

As mentioned earlier, laparoscopic surgery can be performed via a variety of access port sizes. Most commonly utilized are 5-mm ports, though occasionally larger instruments require 10- or 12-mm ports. Smaller port sizes and instrumentation are available, including mini-laparoscopic (3-mm), needlescopic (2-mm), and micro-laparoscopic (<2-mm) instrumentation. A number of procedures including orchiopexy, nephrectomy, and upper tract reconstruction have been reported with these techniques (Borer et al., 1999; Ferrer et al., 2000; Gill et al., 2000; Pini et al., 2012). **Proposed advantages to smaller instruments include: need for smaller incisions, which then translates to improved cosmetic outcomes and decreased postoperative pain; stiffer instruments with improved precision and control; and smaller instruments, which may result in less visceral trauma** (Pini et al., 2012). However, certain limitations exist with this smaller instrumentation. Surgeons have noted operating with smaller instruments to be more technically challenging, with a potentially increased learning curve (Gill et al., 2000). Furthermore, smaller instruments may be more fragile, and the scope of available instruments is more limited in smaller diameters. Thus, standard hemostatic devices, vascular clips, or staplers may not be available to the surgeon. Visualization has been raised as a concern, though advances in high-definition optics have mitigated this to some degree (Pini et al., 2012).

Single-Site Surgery

Laparoscopic single-site surgery, often referred to as laparoendoscopic single-site surgery (LESS), was introduced to urologic surgeons in 2007, when the first single-port nephrectomy was performed (Desai et al., 2008). Soon thereafter, the first nephroureterectomy performed via a single laparoscopic port was also described in children (Bayazit et al., 2009). Since that time, LESS has been described additionally in pediatric varicoceles, orchiectomy, and hernia repair (Kaouk and Palmer, 2008; Marietti et al., 2010). Although most experience in LESS is focused on the adult population, infants have safely undergone LESS for general surgical indications such as pyloromyotomy (Muensterer et al., 2010). The main benefits of LESS are in the cosmetic outcomes, as the single port system can be introduced via the umbilicus, thereby hiding the single scar and creating essentially “scar-less” laparoscopic surgery. The impact of improved cosmetic outcomes, however, may be limited to the early postoperative period. **In one prospective study of children undergoing single-site and standard laparoscopic appendectomy, the single-site approach was initially superior in parent perception of scarring. However, this benefit was negated in longer-term follow-up, and after 18 months there was no difference in scar perception between groups** (Gasior et al., 2014). Additional benefits related to limiting access to a single port include potential for decreased pain and complications, however, evidence to support these specific benefits in LESS is lacking (Tracy et al., 2008).

LESS is accomplished via a multitude of proprietary multitrocar devices that allow placement of multiple instruments through a single incision. These single-port devices vary in size and usability, which may affect their utility in the pediatric population. One specific challenge of LESS is the crowding of instruments, which can contribute to a learning curve for this technique, even for the experienced laparoscopic surgeon. Instrument crowding results in fewer degrees of freedom, clashing of instruments, and potential limited visibility (Hansen et al., 2011). Learning curves for LESS, though not specifically defined in the pediatric population, show sequential improvement in time over the first 25 to 75 cases (Fader et al., 2010; Hernandez et al., 2010). Techniques that surgeons have adapted to counter the concerns of limited working space include: (1) staggering the trocar depth to improve extracorporeal mobility; (2) inserting stay-sutures and/or instruments via fascial-stab incisions for increased assistance intra-abdominally; (3) using a 45-degree lens for improved extracorporeal visibility and mobility of the assistant; and (4) inverting instruments to minimize the surgeon's hands from clashing within a confined working space (Hansen et al., 2011). Additionally, LESS on the robotic platform has been introduced, which improves on some of the technical limitations of pure laparoscopic single-port approaches and has been used successfully across a number of surgical disciplines (Autorino et al., 2013). Notably, however, in the United States, the da

Vinci Single-Site system is only approved for indications of cholecystectomy, benign hysterectomy, and salpingo-oophorectomy (Intuitive Surgical, 2018).

Hemostatic Devices

Several categories of cautery devices exist, most of which are utilized across both the pediatric and adult populations. Monopolar electrocautery is the simplest and most readily available. However, this cautery may be less precise and requires conduction through the patient, who must be grounded. When applying monopolar electrocautery laparoscopically, it is important to note that the laparoscopic instrument is sheathed in an insulating layer, thus protecting the patient from inadvertent dispersion of electricity. However, any exposed metal may also transmit the cautery, and thus all exposed metal toward the working end of the instrument must be in view during cauterization and away from surrounding structures.

Bipolar electrocautery conducts electricity between two points within the patient, and thus is more controlled. However, substantial lateral spread may be seen, with the potential for inadvertent injury. Typically vessels greater than 5 mm should not be addressed with standard bipolar electrocautery. Advanced bipolar devices rely on an internal feedback mechanism to measure tissue seal and adjust current accordingly. This technology optimizes the efficacy of the device while minimizing collateral damage**. It should be noted, however, that all available devices create at least 2 mm of high thermal energy laterally, and thus a safe margin should be applied when utilizing these devices** (Lamberton et al., 2008). The available advanced bipolar instruments have varying functional specifics, such as time to seal, burst pressure of the sealed vessel, production of particulate matter, and impact on visibility. Comparisons of these variables have been performed using in vitro studies; in pediatrics, one should consider the potential impact of visibility from particulate matter in especially small working spaces. Furthermore, smaller-diameter vasculature may be more amenable to ligation with advanced bipolar electrocautery. Although not specifically reported for renal vasculature, the LigaSure device (Medtronic, Minneapolis, MN) has been utilized safely to control the splenic hilum during laparoscopic splenectomy in a pediatric population (Romano et al., 2003).

Similar in appearance to a bipolar electrocautery device is the Harmonic Scalpel (Ultracision Shears Harmonic Scalpel LCS; Ethicon SAS, Issy-les-Moulineaux, France), which converts electric current to high-frequency vibrations, allowing for division of moderate-sized vessels (Fig. 27.5). This device has been reported to be safe for vessels up to 5 mm as long as appropriate time for coagulation is applied (Msika et al., 2001). The Harmonic Scalpel has been reported for use in laparoscopic nephrectomy, though not for control of the hilum in those cases (Helal et al., 1997). Similar to bipolar electrocautery, this device has also been reported to be effective for control of the splenic hilum in children, raising potential uses for more major vasculature in the pediatric population (Schaarschmidt et al., 2002).

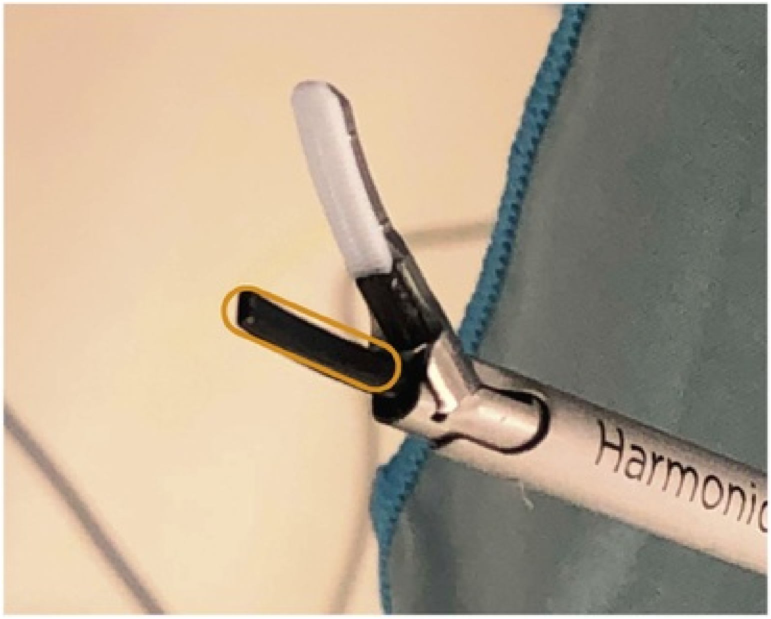

FIG. 27.5 Harmonic scalpel. Jaws *(orange oval)* vibrate at high frequencies to create tissue shearing and coagulation.

Staplers

Laparoscopic stapling devices are typically utilized for vascular control or transection of bowel during reconstructive urologic procedures. Staple characteristics include distance between staples, length and width of the staple load, and potential for articulating. Until recently, laparoscopic staplers required at least a 12-mm port for insertion, given the diameter of the entire device. However, several newer devices on the market currently exist that can be inserted via a 5-mm port. These staplers are shorter in length and smaller in diameter, making them attractive for use in the pediatric population, where working space is often limited (Kuthe et al., 2016).

Clips

Laparoscopic clips are typically applied with manual force, compressing the vessels. It should be noted that Hem-o-lock clips are contraindicated for live donor nephrectomy because of three reports of slippage from the renal artery, resulting in death. The U.S. Food and Drug Administration (FDA) specifically notes donor nephrectomy and does not comment, however, on the use in nephrectomy for benign or malignant disease (Friedman et al., 2012). Titanium clips measure between 5 and 10 mm and can be utilized for moderate-sized vasculature. Typically, the vessel is controlled with clips both proximally and distally to prevent back-bleeding, and an additional clip or series of clips is placed proximally to prevent slippage and hemorrhage.

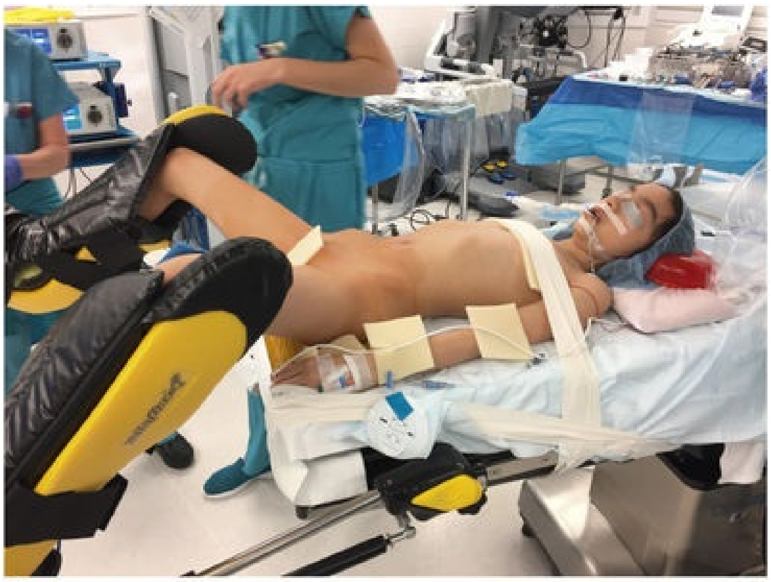
Suture Assistance

Intracorporeal laparoscopic-assisted suturing can be technically challenging and physically demanding (Berguer et al., 2001). As such, several suturing-assistance devices exist to provide improved surgeon comfort and efficiency. These devices typically rely on either a pretied suture to serve as a lasso around the structure of interest or as a mechanically assisted needle device. Such devices have been shown to improve suturing efficiency (Bermas et al., 2004; Wolf et al., 1997). However, these devices may lack the precision needed for delicate tissue handling in the pediatric setting, and some require 12-mm port sizes.

Robotic-Assisted Surgery

The first pediatric robotic-assisted surgery was reported in 2001, a successful Nissen fundoplication (Meininger et al., 2001). Since that initial report, the popularity of robotic-assisted surgery in pediatrics has risen exponentially, with particular interest within pediatric urology, where complex reconstruction is often encountered. Pyeloplasty and ureteral reimplantation are the two most frequently reported indications in the pediatric population, though several additional indications ranging in complexity also exist (Cundy et al., 2018; Kurtz et al., 2017; Varda et al., 2018).

When positioning for robotic surgery, it is important to ensure that all pressure points are padded appropriately, especially because access to these pressure points intraoperatively may be obscured by the docked robot. Renal surgery is typically facilitated in a lateral decubitus position with “airplaning” of the operative table. Meanwhile, pelvic surgery is facilitated by Trendelenburg positioning. Thus, both require the patient to be secured firmly to the table to prevent patient shifting during repositioning intraoperatively. Notably, pelvic surgery was initially described in dorsal lithotomy positioning with docking between the legs. However, even with the first-generation robotic platforms, pelvic surgery can be accomplished via a modified supine position, obviating the need for dorsal lithotomy and inherent risks (Fig. 27.6).



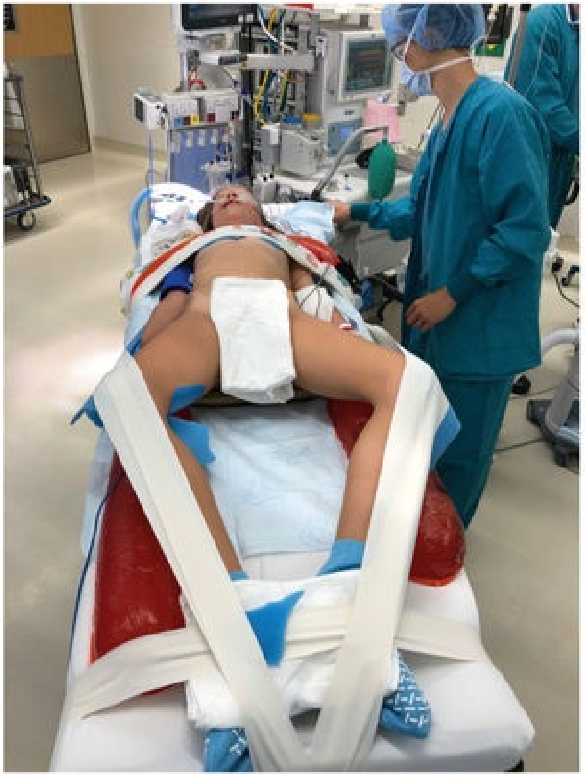


FIG. 27.6 Dorsal lithotomy *(top)* and modified supine *(bottom)* positioning options for robotic-assisted ureteral reimplantation. All pressure points are adequately padded. The child's sacrum is elevated in the modified supine position to facilitate robotic docking while minimizing extracorporeal interference between the robotic arms.

The da Vinci robotic platform (Intuitive Surgical Inc., Sunnyvale, CA) is currently one of only two FDA-approved platforms within the United States, and by far the most commonly utilized. Robotic instrumentation is available through 5- and 8-mm ports, though 5-mm instrumentation is more limited in scope and functionality. In fact, although attractive in pediatrics because of smaller size, the articulating wrists of the 5-mm instruments actually require a larger intracorporeal working space, resulting in lower surgeon efficiency for similar tasks (Ballouhey et al., 2018). **Commonly cited advantages of the robotic platform include improved visualization with three-dimensional optics and magnification, first-person camera control, wristed instrumentation, and a surgeon-controlled additional arm to provide retraction and assistance.** These benefits have allowed expansion of MIS to complex reconstructive procedures that previously may have been undertaken with an open approach (▶ Video 27.4). However, the current robotic platform is costly and lacks tactile feedback, and many iterations of the robot are restricted to single-quadrant surgery because of extracorporeal fixation of the robotic arms. Early in development, instrumentation was somewhat limited. However, most standard laparoscopic instruments such as cauterizing devices, staplers, and clip appliers are currently available within the robotic platform as well. The da Vinci Xi system is the newest robotic platform available, with proposed advantages of functioning within smaller working spaces, improved ability to perform multiquadrant surgery, and more efficient docking (Goonewardene et al., 2017; Raheem et al., 2017). Several of these advantages, such as the multiquadrant functionality and functionality in smaller spaces, are particularly attractive in the pediatric population.

Given the rise in popularity for robotic-assisted surgery, it is only natural that research and design efforts are dedicated to advancing this technology. Many patents associated with the da Vinci robotic system have expired within the past few years or are due to expire in coming years. Several patents exist for new platforms with additional features such as eye-tracking consoles, haptic feedback, and separate docking carts for individual robotic arms, as well as advances in 5-mm and single-port instrumentation (Rassweiler et al., 2017). Additional advances in robotic technology include improved telemonitoring programs, which may ultimately pave the way for telemedicine and remote surgery (Shin et al., 2015). Remote surgery may have a unique place in pediatric urology, where less common diseases may result in a need for regionalization of surgical care (Wang et al., 2015).

Key Points: Instrumentation

- Smaller instrumentation may offer cosmetic and convalescent benefits at a cost of decreased maneuverability or versatility of instrumentation available.
- Visualization of the entire uninsulated section of the instrument is vital to minimizing inadvertent cautery injury.
- All electrocautery devices create at least 2 mm of lateral thermal energy spread, and care must be taken based on these specifications during their use.
- Pelvic exposure may be achieved with side docking using a robotic platform, thereby avoiding exposure to lithotomy positioning–related complications.
- Robotic platforms represent specialized surgical instrumentation and should be applied only if optimizing surgical value and minimizing patient risk.

Complications of Minimally Invasive Surgery

Several complications exist specific to the minimally invasive approach. It is important that surgeons recognize these complications, their typical presentations, and recommended management algorithms when embarking on laparoscopic or robotic-assisted endeavors.

Visceral Injury

Visceral injuries during minimally invasive surgeries within pediatric urology are exceedingly rare. Mechanisms of visceral injury include injury during intra-abdominal access and trocar placement, thermal injury from electrical current deployed within the abdomen, or direct injury with laparoscopic or robotic instrumentation through instrument passage or visceral retraction. Access injuries with either the Veress needle or open direct visualization techniques are quite rare. Across several series of more than 1000 patients, no access injuries to either the viscera or the vasculature were reported using either access technique (Dangle et al., 2016; Yanke and Horowitz, 2007).

Thermal injury to viscera should be addressed if immediately recognized. However, because of the progression of the injury and subsequent cellular necrosis over time, these injuries often present in a delayed fashion, sometimes up to several days after surgery (Bishoff et al., 1999)**. Four mechanisms exist for transmission of monopolar thermal energy to the viscera: (1) Direct application of cautery to the tissue, typically in an inadvertent fashion; (2) direct coupling—or "arching"—when the noninsulated instrument is closely approximated to the tissue, resulting in an unintended current path; (3) capacitive coupling resulting from a direct current through the instrument in spite of insulation and spreading to tissue when the point of contact is small; (4) transition of current through pedicled structures and subsequent injury at the end of the pedicle—the so-called "pedicle effect"** (Humes et al., 2010). By directly visualizing the full exposed end of the instrument and minimizing monopolar cautery, one can minimize the risk for inadvertent thermal injury. However, bipolar cautery can also result in transmission of thermal energy of up to and in some cases greater than 2 mm beyond the intended target. Thus the surgeon must be aware of the adjacent anatomy when any mechanism of cautery is utilized laparoscopically (Harold et al., 2003).

Importantly, visceral injury typically presents in a delayed fashion with a distinct constellation of symptoms including single-site trocar pain, failure to thrive, abdominal distension, low-grade fever, and leukopenia, which unchecked may progress to sepsis. Many patients ultimately require exploratory laparotomy for management, though some reports exist of initial exploratory laparoscopy (Bishoff et al., 1999). Because of a dampened immune response after laparoscopy, these patients do not present with classic peritoneal signs (Hanly et al., 2003; Hiki et al., 2006). Management of a visceral injury requires a high index of suspicion and a low threshold for confirmatory imaging and surgical exploration. Immediate recognition of the injury can be managed by reinforcement of the serosal layer, which can often be accomplished without conversion to open intervention.

Vascular Injury

Similar to visceral injury, major injury to the great vessels is rarely reported, with a 0.7% rate in the adult literature and limits to case reports in the pediatric literature (Guloglu et al., 2004; Montero et al., 2001). Injury during passage of instruments or needles, such as introduction of robotic instruments into the abdomen, is likely a more common mechanism of major vascular injury, yet still rare (Dangle et al., 2016). However, these injuries underscore the importance of situational awareness, careful instrument handling, and clear communication between the bedside assistant and surgeon at the console.

Knowledge of vascular anatomy is essential for safe placement of trocars during laparoscopy and is of utmost importance at point of initial access and insufflation, which often is done via blind insertion of a Veress needle or open insertion of a trocar with limited intra-abdominal visualization. **The umbilicus is commonly thought to fall below the aortic bifurcation, although up to 40% of patients may have an umbilicus that lies above the bifurcation** (Hurd et al., 1992)**. Furthermore, placement of the patient in the Trendelenburg position may actually increase the likelihood of the umbilicus falling above the bifurcation** (Nezhat et al., 1998)**. The implications of this anatomic relationship are the dangers of proceeding with blind needle or trocar insertion at the umbilicus, which could result in injury to underlying major vasculature.** In almost all cases, the left iliac vein crosses midline at the umbilicus, exposing this vessel to the highest risk for vascular injury (Hurd et al., 1992). The plane between both anterior superior iliac spines more reliably falls below the bifurcation of both the aorta and vena cava and may represent a safer alternative for blind needle insertion at the midline (Sriprasad et al., 2006). Interestingly, aberrant anatomy of the distal aorta and iliac vasculature including the presence of intraperitoneal vessels has been reported in children with congenital genitourinary disease such as cloacal malformations and common urogenital sinus (Dykes et al., 1993). Thus, in theory, certain children with genitourinary malformations may be at increased risk for vascular injury during peritoneal access.

Even more common, but perhaps underappreciated, is the risk for injury to the abdominal wall vasculature. Inferior epigastric injury has been reported in children with an incidence of up to 2.5% (Philips and Amaral, 2001). Because of the somewhat predictable anatomy of the epigastric vasculature, port placement 5.5 cm lateral to midline (in adults) or greater than one-third the distance from midline to the anterior superior iliac spine has been proposed to minimize the risk for injury (Joy et al., 2017). In children, however, one can often visualize these vessels, either within the abdomen or via transillumination of the abdominal wall.

Major vascular injury is typically recognized promptly. Standard techniques with Veress needle entry call for aspiration of fluid through the needle to ensure no vascular backflow. If blood is recognized at this step, one should leave the Veress needle in place without manipulation, which could result in shearing or dislodgement of the needle (Montero et al., 2001). Intra-abdominal access is gained elsewhere. If the Veress needle becomes dislodged, one should inspect the posterior abdomen for a retroperitoneal hematoma (Fig. 27.7). Venous injuries can be managed with conservative approaches, including removal of the Veress needle under direct vision and tamponade with the pneumoperitoneum. Arterial or uncontrolled venous hemorrhage must be addressed promptly.

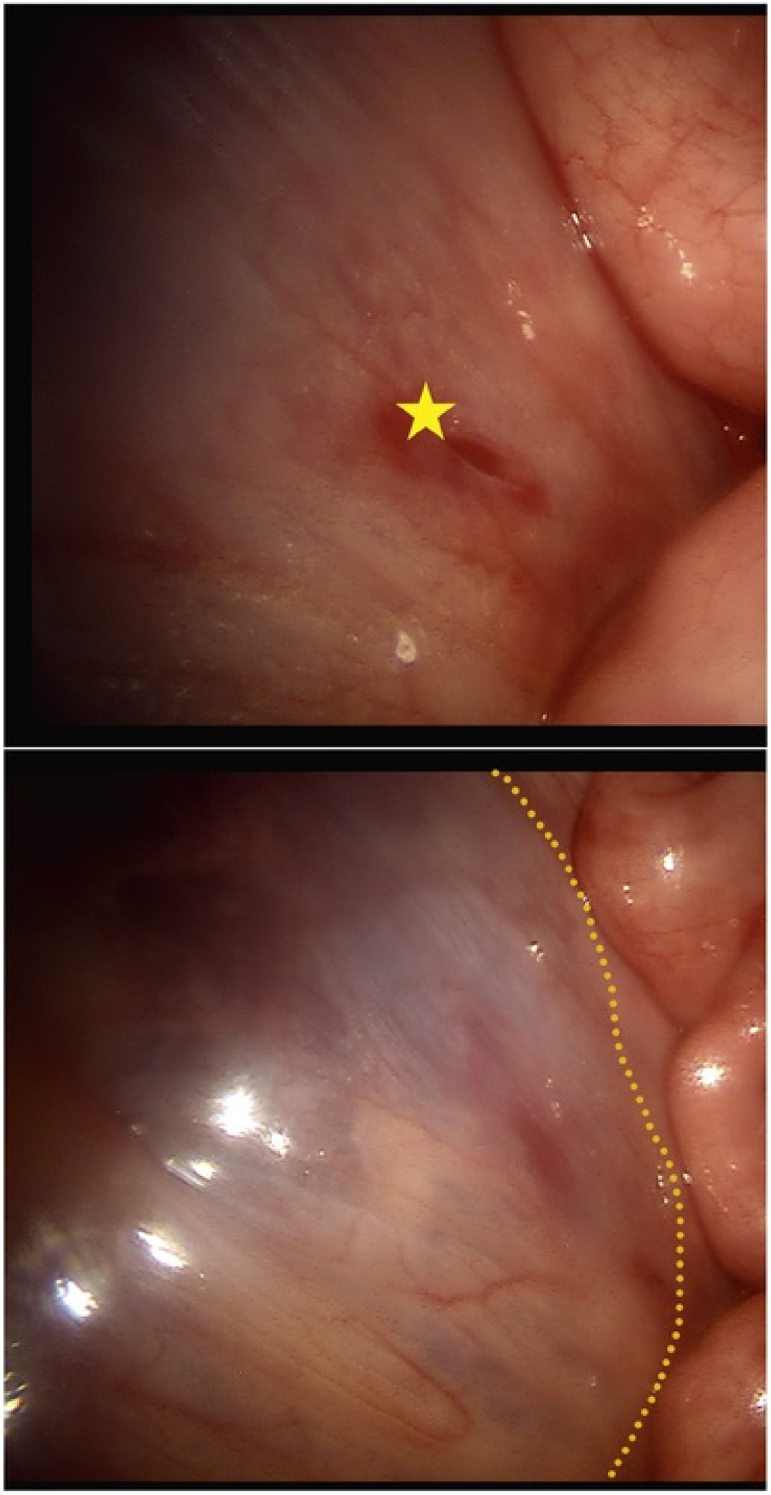

FIG. 27.7 Veress needle vascular injury. *Yellow star (top)* indicates site of Veress injury into the retroperitoneum. *Orange dashes (bottom)* indicate extent of retroperitoneal hematoma. This represents a common iliac vein puncture managed conservatively given adequate tamponade during pneumoperitoneum and absence of expansion of hematoma at the end of the case.

Incisional Hernia (Fig. 27.8)

Port-site hernias are reported in up to 3.2% of cases in the pediatric urology literature (Cost et al., 2010). Omental herniation is a common presentation, often coming to clinical attention within the first week postoperatively (Paya et al., 2008). **Because of the small body habitus and laxity of the abdominal wall, there is no "safe" area for access wherein port site hernias can be avoided. Port sites on the lateral abdominal wall constituted the majority of reported herniations in one series** (Paya et al., 2008)**. Furthermore, size of the port does not correlate to the risk for herniation in children. The 5-mm port sites are not "free," and omental herniation has even been reported in children through 3-mm port sites** (Yee and Duel, 2006). Younger children appear to be at higher risk for hernia formation compared with older children (Cost et al., 2010). Accordingly, it is the authors' practice to close all port sites, irrespective of size or location, in all prepubertal children.

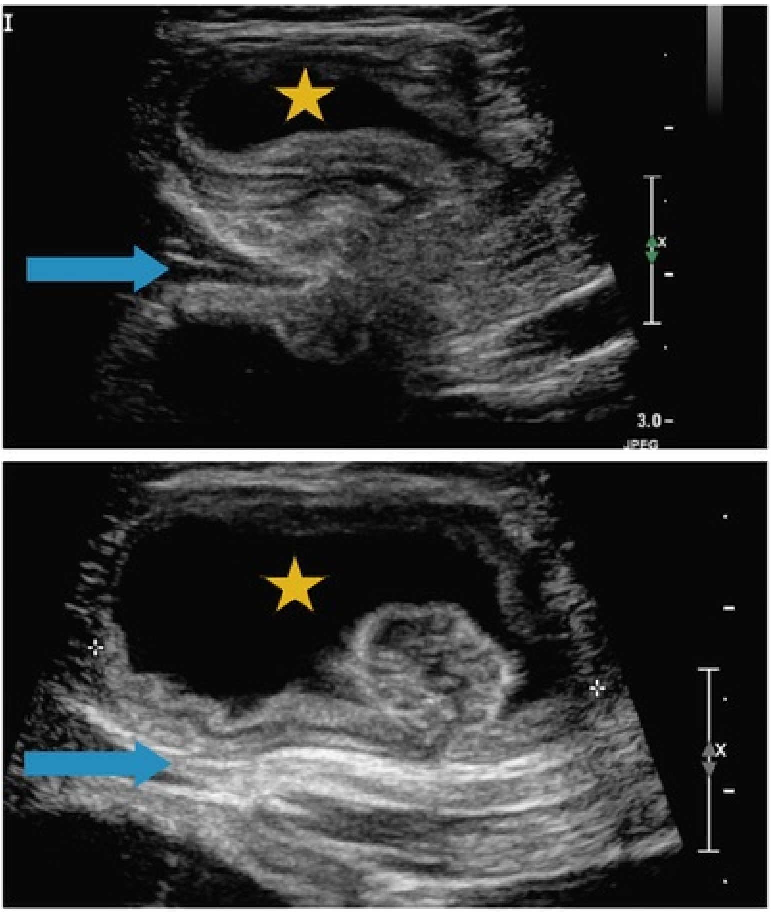

FIG. 27.8 Ultrasound scan showing small intestine *(orange star)* herniating through a fascial defect, superior to the abdominal wall fascia *(blue arrow)*.

Pulmonary Air Embolus

Air embolization from insufflated gas is an infrequent but catastrophic complication. Fortunately, this complication has been reported only rarely in the pediatric population. CO_2 is utilized for insufflation because of its rapid absorption and buffering within the circulation. As opposed to diffusion across the peritoneal membrane, it appears the highest risk for entry of CO_2 into the systemic circulation is caused by vascular injury. In children, umbilical vein injury has been postulated to be the source of entry for most reported cases (Taylor and Hoffman, 2010). One concern, especially in young children, is the potential for contaminant gases, such as oxygen or nitrogen, to be present within the abdomen during insufflation. **This becomes of even greater concern when the area for intra-abdominal expansion approximates the dead space within**

the anesthetic circulation, such as in neonates. In these situations, it has been estimated that up to 10% of insufflated gas may be contaminants of O_2 or N_2 as opposed to CO_2. For this reason, flushing of the insufflation tubing is recommended before inducing pneumoperitoneum (Taylor et al., 2015).

Key Points: Complications

- Injury to abdominal wall vasculature is underreported and can be minimized by visualization of the epigastric vessels before port placement.
- Because of the risk for herniation, closure of all port sites in the pediatric population after MIS is recommend.
- Unrecognized intestinal injury from cautery effect may present in a delayed fashion and should be approached with a high index of suspicion.
- Preflushing of insufflation tubing is recommended, especially in infants, as up to 10% of initial insufflated gas may be oxygen or nitrogen contaminant.

Simulation Training and Evaluation

The expansion of minimally invasive technologies has created an environment ideally suited for simulation and objective performance feedback. Through ubiquitous video-capture capabilities, surgeons can review their performances, others can watch and rate, video can be modeled into virtual reality (VR) environments, and surgeons can rehearse their cases or warm up within the same OR as the patient care arena. These opportunities have allowed for tracking and acceleration of learning curves. Ultimately, we will be able to provide lifelong learning feedback to practicing clinicians and provide objective feedback for learner-centered competency-based advancement through training programs.

Minimally Invasive Surgery Training

Currently, there are no standards for how MIS skills are taught and advanced. Escolino et al., calling on experiences in European pediatric MIS education, posited that there are eight stages to the acquisition of MIS skills (Escolino et al., 2016) (Table 27.5). A more recent review of the optimal paradigm of MIS training to reduce complications and accelerate learning curves suggested a similar pathway (Brunckhorst et al., 2016).

TABLE 27.5

Stages of Minimally Invasive Surgery Skills Acquisition

1. Attend theoretical classes to establish an understanding of pathophysiology, perioperative care, contraindications to surgery, and management of complications.
2. Complete 10 to 20 hours of dry skills lab for fundamental laparoscopic technical skills acquisition.
3. Complete 10 hours of in vivo wet lab practicing similar steps of procedures as would be performed in human surgery.
4. Attend a high volume center for 1 to 3 months.
5. Perform basic laparoscopic surgeries (e.g., orchiopexies, hernias, varicocelectomies) under supervision.
6. Perform complex laparoscopic procedures (e.g., nephrectomies, partial nephrectomies, pyeloplasties) under supervision.
7. Perform procedures independently with some form of expert review.
8. Practice with ongoing feedback, review, and credentialing.

Fortunately, this framework mirrors current training methods in the United States, however, there is significant variability among centers at each of these stages. Thus, much of the determination of advancement is left up to one or two mentors at each site without independent review of the trainee. The Escolino et al. group suggested using objective skills assessment tools, which have been validated across many procedures. Smith et al. conducted a survey of pediatric urology fellows and program directors in North America to understand the robotic-assisted laparoscopic experience fellows were receiving and how Accreditation Council for Graduate Medical Education (ACGME) Milestones scores improved over the course of the training year with regard to MIS skills (Smith et al., 2017). Of the 35 fellows and 30 program directors sent the survey, 16 (46%) and 14 (47%), respectively, responded. More than one-half of fellows stated they performed more than 20 robotic cases in their fellowship year. There was a mismatch, however, between the self-perceptions and the program directors' Milestones scores on graduation, where 75% of fellows and 57% of program directors felt the final MIS Milestones scores were 4 or better. In addition, the survey elucidated that a minority of fellows had any exposure to simulation training during their ACGME year.

Minimally Invasive Surgery Assessment

In 1997, Martin et al. introduced the first broadly applicable objective structured assessment of technical skills (OSATS) tool for dry lab open surgical performance (Martin et al., 1997). Having been now cited over 1600 times, this study laid the foundation to the era of quantifiable surgical technique. **In laparoscopy and robotic surgery, two such OSATS tools—the Global Objective Assessment of Laparoscopy (GOALS)** (Vassiliou et al., 2005) **and Global Evaluative Assessment of Robotic Skills (GEARS)** (Goh et al., 2012) **—have been the backbone to evidence-based demonstration of technical skills in MIS.** Trainees and faculty can now be assessed objectively through these tools, which focus on technical skills domains including depth perception, bimanual dexterity, efficiency, tool control, tissue handling, and autonomy. Through these domains, composite scores have been repeatedly validated to discriminate skill and expertise. The performance domains also correlate to clinical outcomes and generalize to a number of MIS surgeries. These tools are agnostic to the procedure and the reviewers (Reznick and MacRae, 2006). Groups have used live in-person evaluations, postperformance video review with content experts, and video review through crowdsourcing (Goh et al., 2012; Kishore et al., 2008; Lendvay et al., 2015; Vassiliou et al., 2005). Argun et al. (2015) validated a urologic-specific objective assessment tool for cystoscopy and ureteroscopy. In their validation study, 30 trainees from three different sites performed endoscopy tasks on high-fidelity reality-based training modules that simulated the upper and lower urinary tract. The assessment tools used could discriminate training level and cognitive/technical skills.

One significant barrier to obtaining expert evaluations has been the timeliness and consistency of the expert reviews. Thus, in 2014, Chen et al. tested the use of obtaining technical skills assessments through the use of crowdsourcing instead of from expert surgeons (Chen et al., 2014). Using laypeople, they were able to show that an accurate blinded video review of surgery performance using the validated GEARS tool correlated with assessments by expert surgeons. Further validation studies have been performed demonstrating the speed, accuracy, and versatility of using crowds to assess skill in simulation lab, animate lab, and human surgery settings (Aghdasi et al., 2015; Deal et al., 2016; Ghani et al., 2016; Holst et al., 2015; Kowalewski et al., 2016; Lendvay et al., 2015; Polin et al., 2016; Powers et al., 2016; White et al., 2015).

Minimally Invasive Surgery Simulation

MIS can be easily replicated in simulated environments. A number of home-grown and industry-developed physical and VR simulators (Satava, 1993) have been created to provide a learner-centered platform for technical skills practice. The most common reality-based conventional laparoscopic simulation devices have been the box trainers (Fig. 27.9). These frequently come with monitors to give the same two-dimensional visualization as seen in human laparoscopic surgery. Most training programs have these, and trainees can usually access these at all hours and even at home. VR simulators also exist for conventional laparoscopy and have been shown to provide benefit in accelerating learning curves, priming surgeons right before surgery, and allowing for patient-specific surgical rehearsal (Nataraja et al., 2018). Makiyama et al. (2012) demonstrated that a patient's radiographic imaging could be modeled into a VR simulator exercise allowing the surgeon to practice a laparoscopic nephrectomy before performing the procedure on the patient. The module included the patient-specific renal hilar vasculature as identified through computed tomography (CT) imaging so the surgeon could understand and practice how to approach the hilum for ligation. Three-dimensional printing technology has also enabled patient-specific modeling to provide surgeons with lifelike anatomic representations on which they can practice tumor resections, pyeloplasties, or even cloaca repairs before the surgery (Ahn et al., 2017; Bernhard et al., 2016; Cheung et al., 2014) (Fig. 27.10).

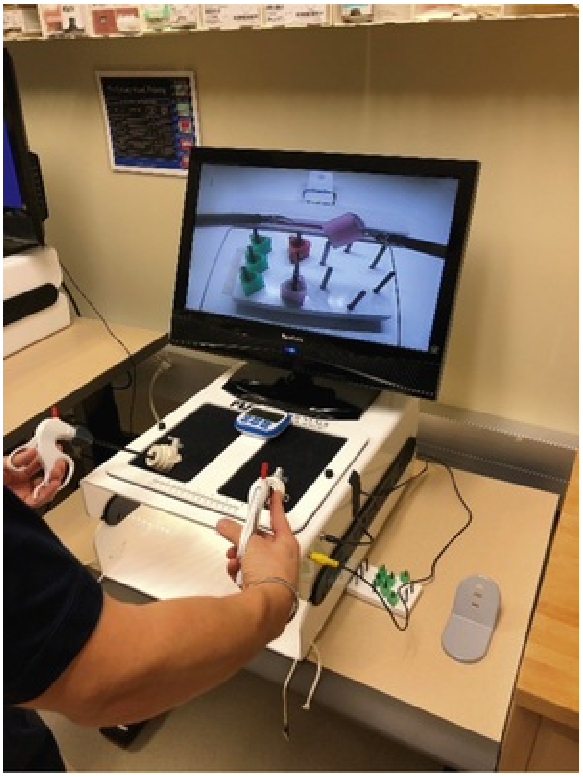

FIG. 27.9 Box trainers allow for simulation of a variety of laparoscopic tasks, ranging from basic to complex, and are a mainstay for dry lab training. Multiple tasks can be exchanged within a single trainer, allowing for cost-containment.

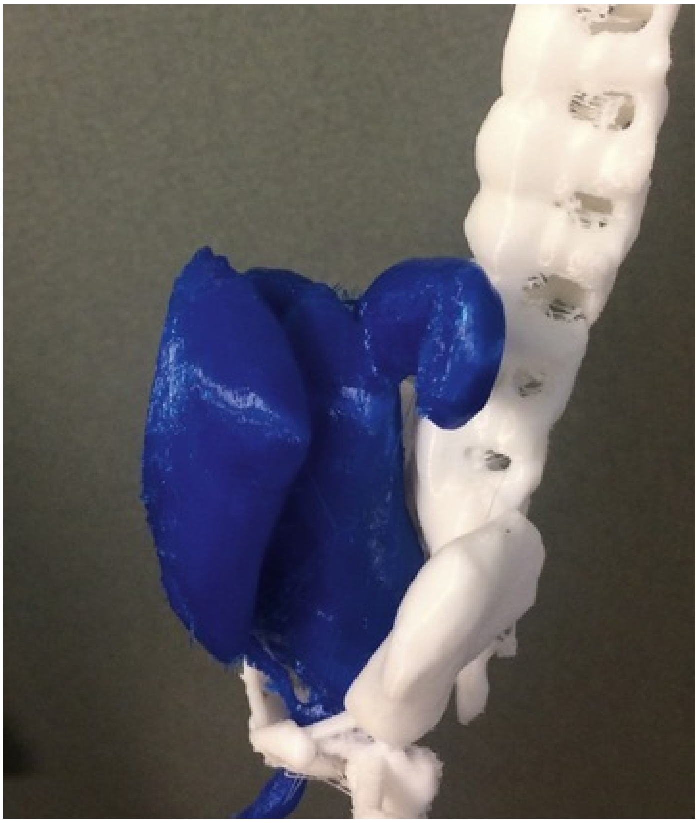

FIG. 27.10 Three-dimensional printing of complex surgical anatomy may aid in surgical simulation and preparation before the planned operation. Color and component materials can be altered for each key anatomic structure, here allowing for differentiation between the spinal cord and the common cloacal structures.

The Fundamentals of Laparoscopic Surgery (FLS) has been the mainstay of basic laparoscopic skills simulation training for over a decade (Okrainec et al., 2011). The American Board of Surgery has adopted this skills curriculum as the standard means to graduate a general surgery resident in laparoscopy. Steigerwald et al. showed that subjects who performed well on the overall and individual FLS modules performed well doing human laparoscopic cholecystectomies, confirming that simulation skills transfer to the OR (Steigerwald et al., 2015). The FLS scores also discriminated (construct validity) different training levels of the subjects. Brydges et al. (2010) validated that a pediatric version of FLS could discriminate experience in laparoscopy levels among a cohort of 18 pediatric urology fellows attending a laparoscopic course. Urology, specifically pediatric urology, does not have a mandated fundamental skills curriculum, however. In 2015, Sweet et al. introduced a variation of FLS called the Basic Laparoscopic Urologic Surgery (BLUS) curriculum, which includes four psychomotor tasks (intracorporeal suturing, peg transfer, pattern cutting, and clip applying) and a cognitive test conceived through validation by experts at 10 academic training sites around North America (Kowalewski et al., 2016; Sweet et al., 2012). This curriculum discriminated skill levels, and studies testing whether the BLUS skills translate to operative performance are ongoing. It remains to be seen if the American Board of Urology will mandate such a simulation curriculum for residency graduation.

The robotic surgery platform is the most optimal device for tracking and simulation modeling. Currently, the da Vinci surgical robot (Intuitive Surgical Inc., Sunnyvale, CA) is the most widely used clinical robot. The video from the console can be recorded in either two-dimensional or three-dimensional mode, and the movement data of the surgical arms can be tracked through software that extrapolates path lengths, velocities, and other tool motions that are all surrogates for expertise. Through the da Vinci Logger system, surgical educators interested in tracking the tool and hand motions of the trainees can capture data about trainee technical skill performance and progress (Hung et al., 2018). **Through machine learning algorithms, Hung et al. (2018) ingested multiple kinematic metrics of robotic surgeries and were able to, with 87% accuracy, predict whether a patient could be discharged 2 days or fewer or more than 2 days. This represents the beginnings of how movement signatures of the surgeon can potentially predict a patient's surgical outcome.**

Furthermore, the robotic platform is an information or data delivery interface. Real-time imaging data, biophysiology data, and pathology data can be delivered to the surgeon through the robotic cockpit or console (Simorov et al., 2012). In theory, a surgeon who has more information about where to dissect and how he or she is performing may yield improved patient outcomes. **In addition, the platform software can be tailored to avoid dangerous or margin-violating movements via no-go or no-fly zones** (Simorov et al., 2012)**. This represents a form of augmented reality (AR) which overlays the robotic experience with visual, haptic, auditory information to assist the surgeon in performing more exact surgery**. Chowriappa et al. (2015) tested the hypothesis that providing a surgeon subject with haptic (force) direction of the surgical instruments while doing a simulated robotic urethrovesical anastomosis would improve the surgeon's performance compared with a group of surgeons who were not exposed to the guiding instruments. Fifty-two subjects went through simulator proficiency training to familiarize each individual with the platforms. They were then randomized to perform surgery with AR or without. Multiple needle-driving and needle-holding metrics and the bimanual dexterity and force sensitivity metrics were statistically higher in the AR group. In addition, when testing for cognitive workload and demand using the National Aeronautics and Space Administration Task Load Index assessment test, the AR group had lower cognitive load. This was the first demonstration of urologic robotic surgery skills being enhanced through the use of augmented reality.

Minimally Invasive Surgery Warm-Up

Athletes, musicians, dancers, and other highly technical professionals warm up before doing their criterion performance. Yet surgeons, arguably the highest-stakes professionals, do not have a codified routine warm-up process. Evidence supports the benefits of doing a brief warm-up of some laparoscopic or robotic skills drills through reality-based or VR-based modules (Abdalla et al., 2015; Lendvay et al., 2008, 2013; Pike et al., 2017; Sethi et al., 2009). In Lendvay et al., surgical trainees and faculty were randomized to receive a robotic VR warm-up or not before doing some robotic suturing drills (Lendvay et al., 2013). Technical skills performance was assessed through tool motion metrics. The subjects who had performed a brief robotic VR warm-up showed statistically significantly better performance metrics when doing both similar and dissimilar reality-based tasks including intracorporeal suturing. In addition, expert robotic surgeons had more improvement than novices. They concluded that even expert robotic surgeons might derive performance enhancement through VR warm-up in clinical practice. Because the VR robotic simulator is attached to the clinical robotic console, it would be practical for the warm-up to proceed without hindering the normal flow of a clinical day. Systematic reviews of warm-up studies have looked at the value of technical skills warm-up for conventional laparoscopic surgery (Abdalla et al., 2015; Pike et al., 2017). **Abdalla et al. (2015) limited their review to prospective studies with residents and/or faculty only with clear hypotheses and objective outcomes. They found six studies meeting their inclusion criteria encompassing 196 cases from 87 participants; five of the six studies showed a statistically significant improvement in technical skills among the warmed-up groups relative to the controls.** They concluded that for laparoscopy, the data provide evidence that warm-up should be further explored and assessed with patient outcomes. Each of the studies reviewed benefited from using OSATS tools to quantify skill across a range of performers.

Warm-up does not have to be limited to psychomotor drills, however. Mental rehearsal has been shown to enhance the technical skills of surgeons (Arora et al., 2011; Pugh, 2012). Much like alpine skiers visualize the gates and turns of the downhill course before competition, Arora et al. demonstrated that surgeons performing mental visualizations of the steps of a laparoscopic cholecystectomy before doing a VR laparoscopic cholecystectomy had statistically significantly higher OSATS scores than their controls for all sessions (Arora et al., 2011). The group used mental imagery statements to immerse the subject in the case. For example, the subject was told to imagine the cautery smoke as they dissect the gallbladder from the liver and visualize the specific grasping instrument required for a particular step. The subjects were assessed by the quality that the imagery was assimilated through a Mental Imagery Questionnaire immediately after the exercise but before the technical skills test. It's possible that reviewing radiographic images and reading the patient's chart before doing surgery may also focus and enhance technical performance.

Minimally Invasive Surgery Learning Curves

As with any procedure, there is a learning curve to becoming proficient. In the era of increasing objective metrics of surgery and the desire to apply evidence to improving patient outcomes, clinicians have sought to establish learning curves for various MIS procedures. As the granularity of outcomes and performance metrics increases, multidimensional learning curve analyses are possible, which help guide trainers and credentialing bodies in determining minimum case volume thresholds and proficiency benchmarks for advancement and privileging.

When evaluating the learning curve for laparoscopic surgery in children, Ku et al. determined that for a single surgeon, operative time (mean 181 minutes down to 125 minutes, $P = 0.02$) and length of hospital stay (mean 5.4 days down to 2.5 days, $P = 0.009$) decreased after ten cases (Ku et al., 2005). Because the study period was over 5 years, the authors stated that the annual case volume does not need to be high to achieve reasonable learning curves. However, there was no mention in the study of the volume of other laparoscopic cases being performed by this surgeon over the study period, which might have influenced the general proficiency of the surgeon.

In 2013, Abboudi et al. performed a systematic review of learning curves for laparoscopic and robotic surgery across adult and pediatric studies (Abboudi et al., 2014). For robotic prostatectomies, studies supported that, after 100 cases, blood loss and operative times saw the biggest drops. For robotic cystectomies, statistically significant improvement was noted after 16 to 30 cases. Again, these studies did not isolate the robotic experience of the subject surgeons, meaning that the surgeons might have been performing other robotic surgeries during the study, thus affecting proficiency**. A few studies in their analysis covered pediatric robotic surgery. In one study, Sorensen et al.** (2011) **demonstrated statistically significant lower operative times after 15 to 20 cases for a surgeon at the beginning of his or her learning curve. And when looking at pediatric urology fellows, Tasian et al.** (2013) **observed that fellows approached expert-level operative time benchmarks after 37 pediatric robotic pyeloplasties.**

When comparing learning curves for novices performing conventional laparoscopic versus robotic-assisted laparoscopic pyeloplasty anastomoses in a porcine model, Passerotti et al. demonstrated that the learning curve is faster in the robotic-assisted group (Passerotti et al., 2009). The objective anastomotic quality score of each of the three surgeons increased over the five procedures they each did, with the robotic procedures consistently being scored higher than the laparoscopic procedures.

Key Points: Simulation Training and Evaluation

- Several standardized evaluation tools exist to assess trainee progress with minimally invasive techniques.
- High-fidelity simulation models contribute to early training for novice surgeons and case-specific training simulation for more experienced surgeons.
- Kinematic metrics and fluidity of motion are associated with surgical outcomes.
- Evolution of technology in the form of augmented reality and three-dimensional visualization may help improve surgical safety in the future.
- Warm-up exercises, both mental and physical, can help prepare the surgeon for the complex surgical tasks that are demanded intraoperatively.

Conclusion

Numerous studies have shown that MIS in pediatric urology patients is safe, effective, and superior in some circumstances to open approaches. However, along with the value proposition for families to have some procedures performed through MIS, laparoscopic providers need to be aware that there are physiologic, anatomic, and instrumentation-related considerations that can yield surgical effects dissimilar to those in adult patients and/or open approaches. The advancement of surgical technology in MIS has exploded, whereas open surgical technologies have remained relatively stagnant. This promises to allow surgeons to shape the future of MIS. Furthermore, never before have we been able to drill down to the skill of surgeons and provide the type of feedback we can today so that we can make sure that every provider is competent, proficient, and enlightened about best practices in MIS.

Clinical and Urodynamic Evaluation of Lower Urinary Tract Dysfunction in Children

---

Duncan T. Wilcox MD, MBBS, Kyle O. Rove MD

Evaluation of the urinary tract should be tailored to the patient at hand, as no presentation is alike, and underlying etiologies and resulting phenotypes can vary dramatically. Similarly, age and timing of presentation may also influence testing needs. Increasingly, urologists can accurately diagnose lower urinary tract pathology with a thorough clinical history, physical examination, and noninvasive tests, thus avoiding invasive, complex, and often more expensive studies in many clinical scenarios. When testing is required, it may be performed as part of a diagnostic workup, screening, surveillance, or follow-up testing after a procedure. Initially we will review the approach to making a diagnosis, highlighting important aspects of the history, physical examination, and, where appropriate, investigations in patients with lower urinary tract dysfunction. We will then identify some common scenarios for comprehensive lower urinary tract evaluation. More in-depth discussion of clinical entities can be found elsewhere in this text but are discussed briefly here for context.

Clinical Evaluation

History

Complete workup of a patient with incontinence, voiding dysfunction, or known lower urinary tract pathology begins with a thorough patient history. We prefer to take the history directly from the child when possible. This should be tailored to the patient's age and maturational status in the context of voluntary bladder and bowel control. The approach to working up lower urinary tract symptoms includes first attempting to identify an anatomic or neurologic etiology for lower urinary tract symptoms. If these are ruled out, then it is appropriate to ascertain the type of underlying bladder (and/or bowel) dysfunction. **The important components of a complete history should include symptomatology, voiding frequency, bowel function, prior urinary tract infections, relevant family history, maternal prenatal history including screening ultrasonography, birth history, developmental milestones including toilet training, neuropsychiatric conditions, past medical and surgical history, social history, diet, and review of systems.**

Storage Symptoms

The urologist should ask about symptoms attributable to lower urinary tract storage dysfunction such as urgency, frequency, or incontinence. Incontinence timing should be determined (continuous versus intermittent, day versus night, how often). Signs of increased or decreased bladder capacity might also be inferred from the history, and a directed workup to confirm this may be helpful. Secondary enuresis (new incontinence after at least 6 months of being dry) may occur in response to changes in daily activities or new stressors at home or school. This should be explored.

Diet should also be reviewed with the patient, as known bladder irritants like caffeinated beverages (e.g., soda, tea, coffee, sports drinks, energy drinks) can directly contribute to symptoms of urinary urgency (Arya et al., 2000; Leclair and Héloury, 2010).

Voiding Symptoms

In boys, history of deviated or narrowed urinary stream, prolonged urination, inability to completely empty, straining, dysuria, and postvoid dribbling should be elicited. With girls who urinate spontaneously, posture on the toilet is relevant. Sitting with legs tightly together, slouching, or sitting on the edge of the toilet with feet barely touching the floor promotes pelvic floor musculature activation, which increases bladder outlet resistance. This may result in increased voiding pressures and contribute to dysuria or incomplete emptying, subsequently increasing the risk for bladder dysfunction or urinary tract infections. Proper posture on the toilet should be encouraged, and if needed, a footstool can be used (Fig. 28.1). Sometimes, the child might be encouraged to sit on the toilet "backwards" facing the tank, thus ensuring the legs are apart to minimize poor posture. Holding maneuverers—sometimes referred to by parents as "doing the potty dance," posturing, crossing the legs, grabbing the perineum, or squatting—are witnessed in pediatric patients trying to postpone bladder emptying in response to need to urinate (or detrusor overactivity [DO]) (Yerkes, 2009). Posturing maneuvers increase perineal pressure and inhibit bladder contractions through the sacral reflex arc, likely through increased afferent cosignaling (gate control theory of pain transmission, which states that increased large-fiber afferent signals will decrease signals transmitted by smaller fibers through the dorsal horn). The latter is felt to be one of the possible mechanisms of action for transcutaneous electrical nerve stimulation (TENS), posterior tibial nerve stimulation (PTNS), and sacral neuromodulation (Hoebeke et al., 2001; Malm-Buatsi et al., 2007; Roth et al., 2008; Schober et al., 2015).

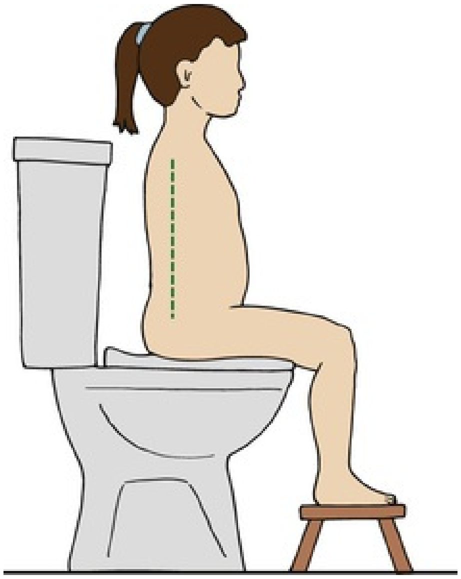

FIG. 28.1 Proper posture on toilet with support for feet if necessary. Avoid

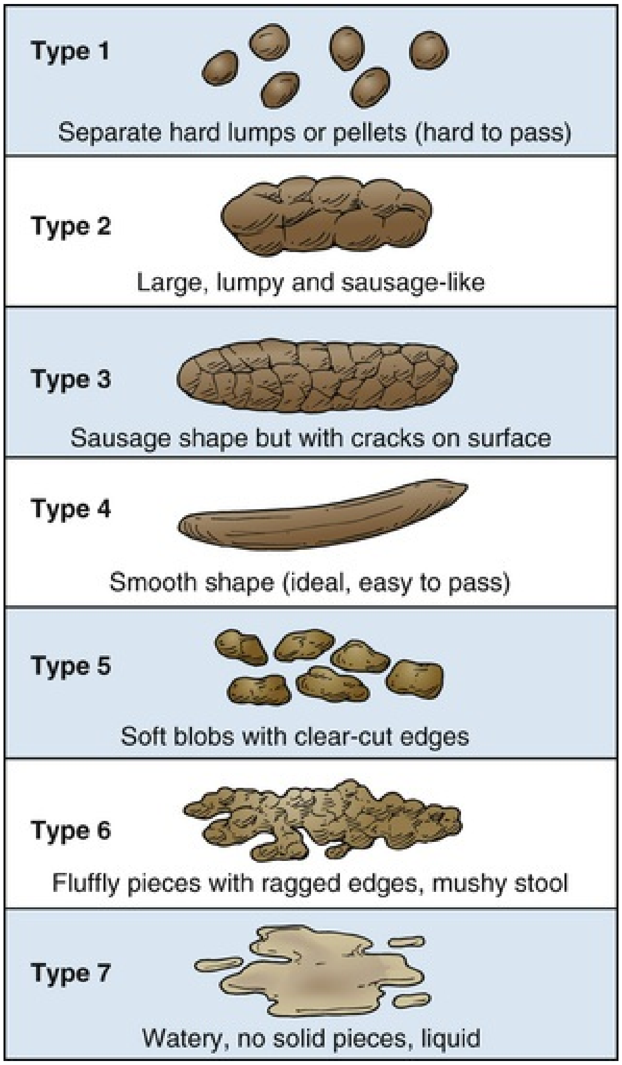
dangling feet over edge as this likely increases pelvic floor muscle tone, inhibiting relaxation for voiding.

Bowel Function

Bowel dysfunction is often coincident with lower urinary tract dysfunction given similar innervation of the rectum through the sacral nerve roots (S2–S4) (Burgers et al., 2013). As such, obtaining bowel function history is extremely important, as there are cases in which predominant bowel dysfunction may be the only underlying cause of urinary symptoms. Specificity when obtaining a bowel function history is key because constipation as a concept confuses many parents and patients. Asking if a patient has constipation is usually insufficient, so we suggest providers delve more specifically into bowel movement frequency, fecal incontinence, abdominal pain, size of stool, and consistency of bowel movements according to the Bristol stool scale (Lewis and Heaton, 1997).

The Bristol stool scale is a useful guide designed to classify the form of human feces into seven distinct categories (Fig. 28.2). Sometimes referred to in the United Kingdom as the “Meyers scale,” it was developed at the University of Bristol in 1997 (Lewis and Heaton, 1997). The scale ranges from 1 to 7, with 1 corresponding to small, hard pellets and 7 corresponding to watery diarrhea. We use it as a clinical communication aid with our patients and their families in terms of what to strive for and to facilitate titration of supplemental fiber or laxatives.



Type 1
Separate hard lumps or pellets (hard to pass)
Type 2
Large, lumpy and sausage-like
Type 3
Sausage shape but with cracks on surface
Type 4
Smooth shape (ideal, easy to pass)
Type 5
Soft blobs with clear-cut edges
Type 6
Fluffly pieces with ragged edges, mushy stool
Type 7
Watery, no solid pieces, liquid

FIG. 28.2 Bristol stool chart with visuals and descriptions of different stool types. This scale provides a helpful, objective reference for documenting stool consistency when talking to patients about bowel function. (Modified from Lewis SJ, Heaton KW. Stool form scale as a useful guide to intestinal transit time. *Scand J Gastroenterol*. 1997;32(9):920–924.)

We find it helpful to offer a healthy baseline of bowel function as a goal, specifically that patients should have a soft, smooth, daily bowel movement that is easy to expel without pain (Bristol 3 to 4). A consensus definition of functional constipation in children can be found in the Rome IV criteria published in 2016 and is shown in Table 28.1 (Drossman 2016; Rasquin et al., 2006). However, the definition of functional constipation and/or bowel dysfunction remains controversial (Austin et al., 2014; Drossman and Hasler, 2016). From a practical standpoint, we have found the questions mentioned earlier related to bowel function sufficient to identify patients with concomitant bowel-related problems and design appropriate.

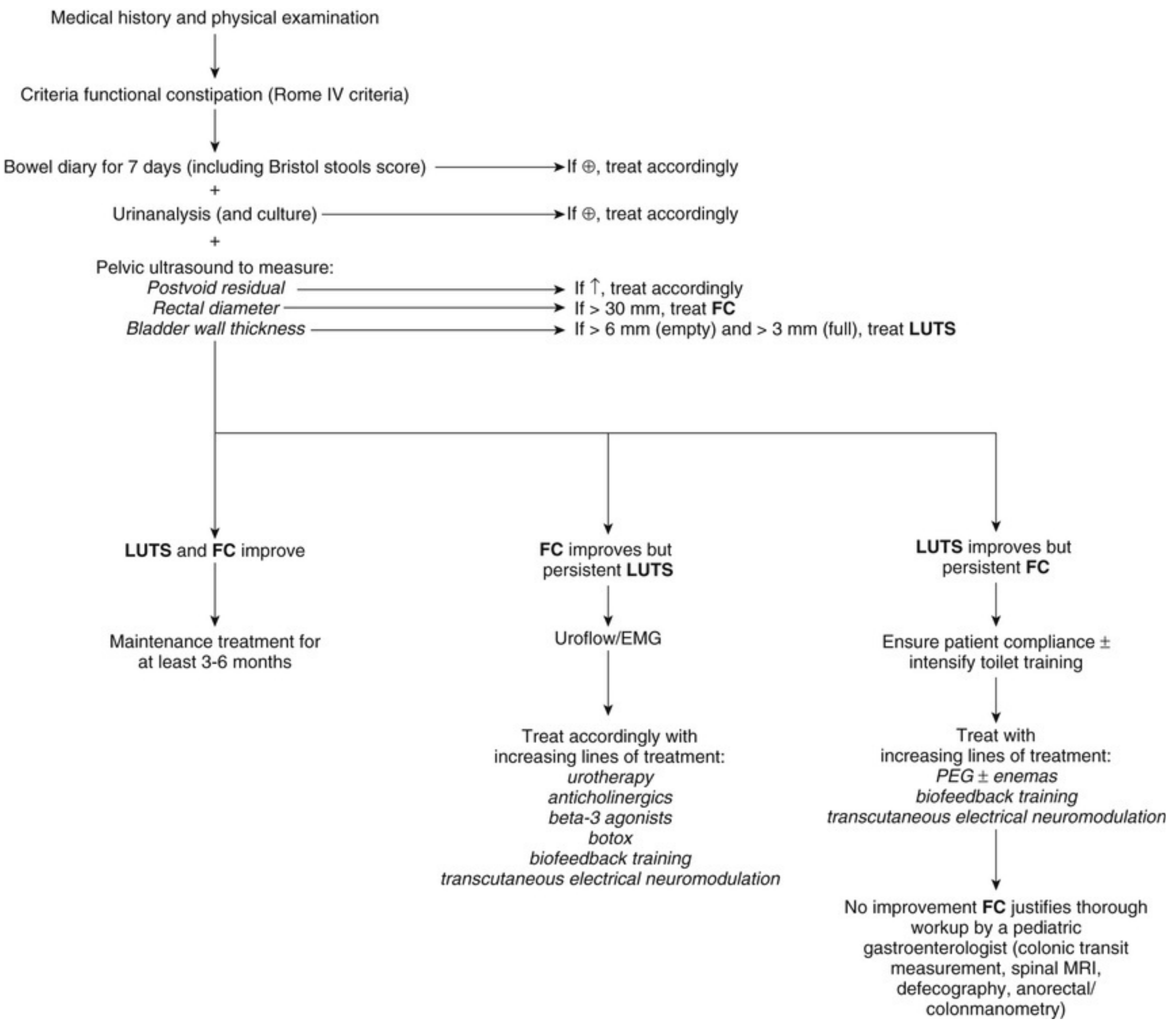
TABLE 28.1

Rome IV Criteria for Functional Constipation in Children

FUNCTIONAL CONSTIPATION
Must include two or more of the following in a child with a developmental age of 4 years or older with insufficient criteria for a diagnosis of irritable bowel syndrome:
• Two or fewer defecations per week • One or more episodes of fecal incontinence per week • History of retentive posturing or excessive volitional stool retention • History of painful or hard bowel movements • Presence of a large fecal mass in the rectum • History of large-diameter stools that obstruct the toilet • Functional nonretentive fecal incontinence (FNRFI)
Must include all of the following in a child with a developmental age of at least 4 years:
• Defecation in places inappropriate to the social context at least once per month • No evidence of an inflammatory, anatomic, metabolic, or neoplastic process • No evidence of fecal retention

Modified from Rasquin A, Di Lorenzo C, Forbes D, et al. Childhood functional gastrointestinal disorders: child/adolescent. *Gastroenterology.* 2006;130(5):1527–1537; Drossman DA. Functional gastrointestinal disorders: history, pathophysiology, clinical features, and Rome IV. *Gastroenterology*. 2016;150(6):1262–1279.e2.

In 2013, the Standardization Committee of the International Children's Continence Society (ICCS) published a treatment algorithm for the management of functional constipation in patients with lower urinary tract symptoms (Fig. 28.3).

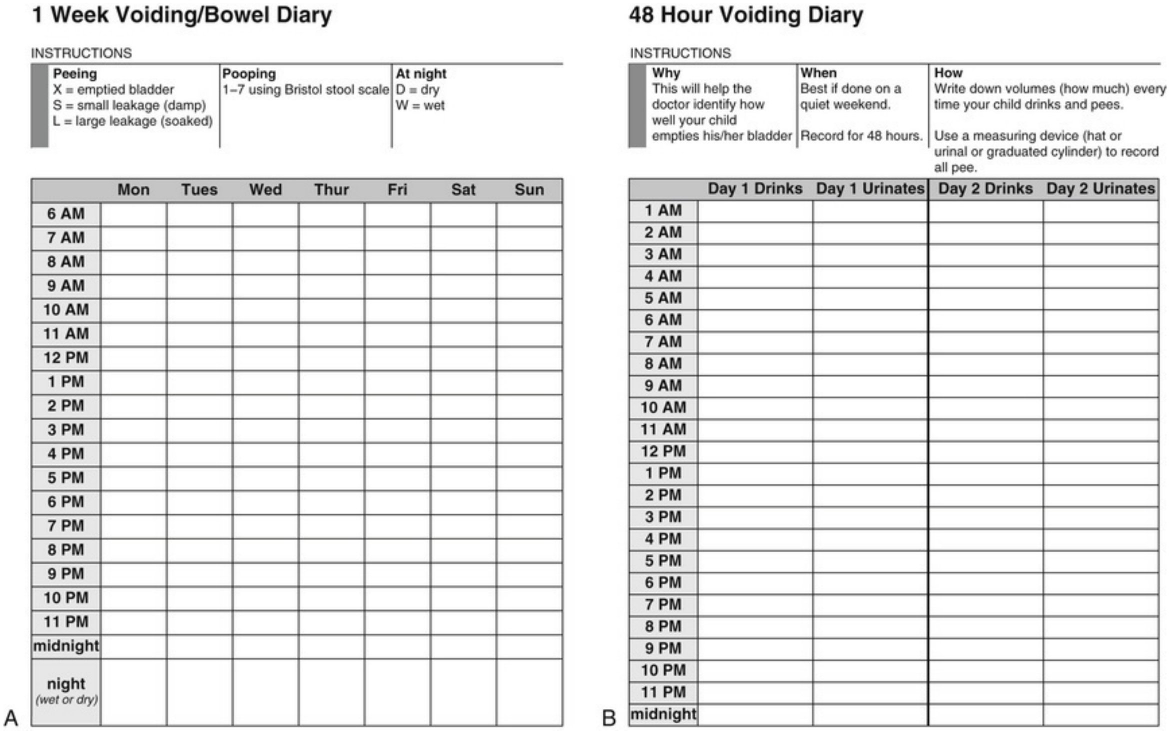


Medical history and physical examination
Criteria functional constipation (Rome IV criteria)
Bowel diary for 7 days (including Bristol stools score)
If ⊕, treat accordingly
+
Urinanalysis (and culture)
If ⊕, treat accordingly
+
Pelvic ultrasound to measure:
Postvoid residual
Rectal diameter
Bladder wall thickness
If ↑, treat accordingly
If > 30 mm, treat FC
If > 6 mm (empty) and > 3 mm (full), treat LUTS
LUTS and FC improve
Maintenance treatment for at least 3-6 months
FC improves but persistent LUTS
Uroflow/EMG
Treat accordingly with increasing lines of treatment:
urotherapy
anticholinergics
beta-3 agonists
botox
biofeedback training
transcutaneous electrical neuromodulation
LUTS improves but persistent FC
Ensure patient compliance ± intensify toilet training
Treat with increasing lines of treatment:
PEG ± enemas
biofeedback training
transcutaneous electrical neuromodulation
No improvement FC justifies thorough workup by a pediatric gastroenterologist (colonic transit measurement, spinal MRI, defecography, anorectal/ colonmanometry)

FIG. 28.3 Algorithm for the management of functional constipation *(FC)* and lower urinary tract symptoms *(LUTS). EMG,* Electromyogram, *MRI,* magnetic resonance imaging, *PEG,* polyethylene glycol. (Modified from Burgers RE, Mugie SM, Chase J, et al. Management of functional constipation in children with lower urinary tract symptoms: report from the Standardization Committee of the International Children's Continence Society. *J Urol.* 2013;190[1]:29–36.)

Clinical Aids

Patients diaries can be especially useful in determining elimination habits, and corresponding urinary symptoms. Although a number of diaries have been described, the most common are the 7-day bowel and bladder diary (Fig. 28.4A) and 48-hour frequency-volume chart (see Fig. 28.4B). The 7-day bowel and bladder diary involves the patient or parent tracking timing of voids, bowel movements, associated stool consistency, and presence of any incontinence of urine or stool in the day or night. This tool provides a very complete picture, eliminating problems with recall bias (Lane et al., 2011; Roth and Austin, 2014). Objective data regarding bowel function can aid with the diagnosis of functional constipation.



1 Week Voiding/Bowel Diary

48 Hour Voiding Diary

INSTRUCTIONS

Why	When	How
This will help the doctor identify how well your child empties his/her bladder	Best if done on a quiet weekend. Record for 48 hours.	Write down volumes (how much) every time your child drinks and pees. Use a measuring device (hat or urinal or graduated cylinder) to record all pee.

FIG. 28.4 (A) Example of a 1-week voiding and bowel diary. Patients are separately provided pictographic Bristol Stool Scale for reference. (B) Example of 48-hour frequency and volume chart that provides greater detail about liquid intake and urinary output.

For patients with a primary complaint of voiding dysfunction, a 48-hour frequency-volume chart may be obtained (Hoebeke et al., 2010). A toilet seat "hat" with measurements or graduated cylinder should be provided to measure volumes. Weekends with normal planned activities are suggested to complete the task, which consists of recording volumes of fluid intake and output and taking note of any incontinence episodes. The diary does not necessarily have to be filled out on consecutive days, but each should cover a 24-hour period (Austin et al., 2014). This type of diary can help determine a number of different voiding parameters, including functional or maximum bladder capacity and presence of polyuria. Because liquid intake is recorded, its contribution (either through type of product or overall volume) can be determined (e.g., intake of caffeinated beverages or large intake of fluids before bedtime). **Completion of a frequency-volume chart is useful in pediatric patients with bowel and bladder dysfunction and should always be performed in spontaneous voiders resistant to first-line, conservative therapies.** Functional bladder capacity can be compared with estimated bladder capacity. Multiple studies have attempted to ascertain an accurate method of estimated bladder capacity for children. The most widely cited methods and those we use include estimated bladder capacity (in mL) in infants up to 1 year of age calculated as (weight in kilograms × 7) (Fairhurst et al., 1991), and estimated bladder capacity in older children calculated as (age in years + 2) × (30) (Koff, 1983; Berger et al., 1983).

In summary, parents and even patients may not be attuned to subtle but pathologic voiding habits, and diaries are an easy, low-cost method to clarify these clinical details.

Urinary Tract Infections

History of urinary tract infection should be elicited and in particular, whether the infections were associated with fever and/or symptoms. For reference, asymptomatic bacteruria is relatively uncommon, found in 1% of girls and 0.03% of boys (Kemper and Avner, 1992). Collection technique should also be ascertained as bagged specimens should not be considered reliable (unless negative). Symptoms of fever with a culture-documented urinary tract infection may indicate incomplete bladder emptying or urinary stasis. Care and finesse should be used to differentiate nonspecific lower urinary tract symptoms associated with voiding dysfunction and nondescript, undocumented “urinary tract infections,” particularly in the presence of negative urine cultures. Depending on the circumstances, redirection of patient and family expectations and education about signs and symptoms of infection in the context of underlying pathologies may be required.

Neurologic Function

Screening for neurologic symptoms should be performed as part of a complete medical history. Specifically, clinicians should inquire about changes in perineal numbness, gait, altered sensorium of the extremities, or new difficulties with balance or coordination. Positive findings here may indicate underlying occult neurologic disease requiring further workup. Such symptoms are particularly worrisome when they are newly onset in previously healthy patients who present with secondary enuresis or other lower urinary tract problems.

Validated Questionnaires

Validated questionnaires (also referred to by some as *patient-reported outcomes*) provide for an objective means to measure patient perspectives on symptoms, quality of life, and emotional impact of medical conditions. The best questionnaires are validated and tested extensively to ensure reproducibility and internal and external validity with respect to the condition(s) being tested and the population of interest, among others. Important validated questionnaires for pediatric patients with lower urinary tract pathology are discussed in the following sections.

Dysfunctional Voiding Symptom Score.

The Dysfunctional Voiding Symptom Score (DVSS) was designed for use in pediatric patients and was first reported in 2000. It is largely based on the American Urological Association Symptom Index, which assesses lower urinary tract symptoms that result from benign prostatic hyperplasia (Farhat et al., 2000). It consists of ten questions that assess a variety of symptomatic domains include storage and voiding symptoms, but also includes posturing and bowel habits. Each question is scored from 0 to 3, depending on how often each particular item occurred in the month prior for a maximum score of 30.

Dysfunctional Voiding and Incontinence Scoring System.

The Dysfunctional Voiding and Incontinence Scoring System (DVISS) is composed of 14 questions (13 assess symptoms, and 1 addresses quality of life). The maximum score is 35 + 3, and a cutoff value of 9 was determined for boys and girls to differentiate normal from abnormal voiders (Akbal et al., 2005). The majority of the questions are scored with yes or no answers.

Pediatric Urinary Incontinence Quality of Life Score.

The Pediatric Urinary Incontinence Quality of Life Score (PinQ) was developed and psychometrically validated by Bower et al. and measures quality of life as a function of urinary incontinence in a child (Bower et al., 2006). PinQ has been shown to have excellent internal validity, content validity, and test retest reliability. During development and validation, no correlation was shown between the questions, suggesting minimal content overlap (Bower et al., 2006). A proxy version that can be completed by parents or guardians showed good correlation with the child (intraclass correlation coefficient [measure of agreement between groups with 0 meaning no correlation and 1 perfect correlation] 0.681, 95% confidence interval [CI], 0.416 to 0.840). The PinQ has 20 questions, each graded from 0 to 4 (answers include no, hardly ever, sometimes, often, and all the time) with a maximum score of 80. Questions fall into one of two categories: intrinsic (internalizing) and extrinsic (externalizing) behaviors, and subscores can be calculated for each. These categories relate to how each patient processes and manages incontinence emotionally. Higher scores indicate worse dysfunction and lower quality of life. The PinQ does not appear to be influenced by other underlying comorbidities (Deshpande et al., 2011). It has been translated into multiple languages and shown to be reliable in multiple cultural contexts.

With regard to overlap, the DVSS and PinQ were shown to be complementary, providing a composite view of lower urinary tract symptomatology and subsequent effect on quality of life (Thibodeau et al. 2013). The DVSS showed increased ability to discriminate changes in response to ongoing treatment (Altan et al., 2017).

Incontinence Symptom Index-Pediatric.

The Incontinence Symptom Index-Pediatric (ISI-P) questionnaire was modified from the Incontinence Symptom Index (ISI) questionnaire for use in a pediatric population in 2007 and was designed to be filled out by patients between 11 and 17 years of age (rather than by caregivers) (Nelson et al., 2007). The ISI-P has 11 questions for a maximum score of 44. Like the DVISS, a cutoff value of 9 was determined for both sexes.

Psychological Screening.

Children with lower urinary tract pathology can commonly have coexisting behavioral and emotional disorders that can contribute to the presentation. In several representative studies, 20% to 30% of children with nocturnal enuresis, 20% to 40% with daytime incontinence, and 30% to 50% with fecal incontinence are affected by comorbid behavioral disorders (Gontard et al., 2011). Just as we recommend excluding organic causes of disease, psychological screening should be obtained to adequately diagnose and treat identified conditions.

Child Behavior Checklist.

The Child Behavior Checklist (CBCL) rates children on behavior and emotions and is filled out by parents or guardians (Achenbach and Ruffle, 2000). Widely used in child psychology, this questionnaire can be used in patients between 18 months and 18 years of age. There are two versions, one covering preschool-age children (18 months to 5 years) and older children (6 to 18 years). A Likert scale is used to answer the 100+ questions, which assess internalizing behaviors (i.e., anxiety or depression) and externalizing behaviors (i.e., acting out, aggression, hyperactivity).

Short Screening Instrument for Psychological Problems in Enuresis.

The Short Screening Instrument for Psychological Problems in Enuresis (SSIPPE) is a brief, derivative instrument of seven internalizing questions taken from the CBCL and six externalizing items from the Attention Deficit Hyperactivity Disorder scale of the Disruptive Behavior Disorders Rating instrument (Van Hoecke et al., 2007). Either the CBCL or SSIPPE can be used to assess behavior and emotions. As the SSIPPE is shorter, it can be used to screen for problems. If two or more issues in either the internalizing or externalizing section are positive, the full CBCL can be completed. Should that verify underlying behavioral or emotional disturbance, a full child psychology referral is recommended.

Selecting an Appropriate Patient-Reported Outcome Measure.

Atlan et al. performed a novel comparison of several questionnaires, including the Dysfunctional Voiding Symptom Score (DVSS), Incontinence Symptom Index–Pediatric (ISI-P), Dysfunctional Voiding and Incontinence Scoring System (DVISS), and Pediatric Urinary Incontinence Quality of Life (PinQ) (Altan et al. 2017). Forty-two patients with bowel and bladder dysfunction were compared with 42 healthy controls and asked to complete all four questionnaires before treatment; underwent standard treatments for 3 months including urotherapy, anticholinergics, or desmopressin; and then all patients repeated the questionnaires and assigned subjective recovery rates as a percentage to represent overall recovery or progress. The DVISS (designed by the authors' department) was reported to have better discrimination with respect to diagnosis, and the DVSS, DVISS, and ISI-P all correlated well with subjective recovery rates. The PinQ, which measures emotional impact of incontinence on quality of life, did not correlate well with therapy or subjective recovery. This could indicate that either the questionnaire does not assess domains that are readily affected by therapy, emotional states that result from underlying voiding dysfunction are less malleable, therapies affecting symptoms take longer to manifest as measurable emotional change, or emotional change does not result from symptom relief.

Physical Examination

Patients who present with complaints attributed to lower urinary tract function should undergo a physical examination. This examination should be comprehensive, with particular attention paid to vital signs and neurologic, abdominal, and genitourinary systems. The relevant findings in each of these areas are discussed in the following sections.

Vital Signs

Vital signs including height, weight, temperature, heart rate, and blood pressure should be obtained at all clinic visits. Height and weight can be used to calculate body mass index (BMI), which is equal to weight in kg divided by height in m^2. An underweight or overweight BMI has been correlated to risk for higher lower urinary tract symptom scores (Oliver et al., 2013). Although commonly used as a screening tool to counsel families, BMI was originally devised in the 19th century and validated for an adult population (Quetelet, 1869). Its values are felt to be inaccurate in children and adolescents, and to correct for this, BMI z-scores based on BMI percentile can be used to better classify children as overweight or obese (Cole, 1991). This approach, however, is cumbersome and does not lend itself to quick interpretation by clinicians. Recently, Peterson et al reported that triponderal mass index (TMI) classified 2285 patients 8 to 29 years of age as healthy or overweight better than BMI z-scores (Peterson et al., 2017). TMI is calculated by mass in kg divided by the height in m^3. The authors demonstrate that TMI misclassified patients less often as overweight than BMI z-scores (8.4% vs 19.4%). The TMI thresholds to diagnose overweight status were 16.0 kg/m^3 for boys and 16.8 kg/m^3 for girls and were 18.8 kg/m^3 for boys and 19.7 kg/m^3 for girls to diagnose obese status. These results underscore the difficulties in interpreting BMI data for pediatric and adolescent patient groups.

Elevated blood pressure (as determined by age, sex, and height-related nomogram) may be indicative of underlying renal disease. Abnormal values warrant repeating the blood pressure measurement to confirm, ideally at separate visits. As renal disease often occurs secondary to urinary tract pathology, abnormal blood pressure readings should be investigated further with imaging such as renal bladder ultrasonography and appropriate laboratory studies (urinalysis, serum creatinine, and/or cystatin C).

Neurologic Examination

Neurologic assessment of reflexes, strength, coordination, and sensation of all extremities should be performed. Although the findings of upper extremity function do not inform the function of the lower urinary tract, the presence or absence of upper extremity function (fine-motor control, sensation, handedness) can affect care decisions involving self-catheterization. Use of aids for mobility or ambulation should be documented (e.g., wheelchair, walker, crutches, ankle foot orthosis [AFO] devices), although context for use can vary considerably. The Centers for Disease Control and Prevention (CDC) National Spina Bifida Patient Registry uses a standardized approach to classifying patients' functional neurologic level and mobility status, which do not correlate (Thibadeau et al., 2013; Sawin et al., 2015). These objective definitions are shown in Table 28.2.

TABLE 28.2

Objective Classification of Lower Extremity Function in Terms of Functional Neurologic Level and Ambulation Phenotype[a]

FUNCTIONAL NEUROLOGIC LEVELS	
LEVEL OF LESION	**FUNCTIONAL ABILITY**
Thoracic	Flaccid lower extremities
High-lumbar	Hip flexion present
Mid-lumbar	Knee extension present
Low-lumbar	Foot dorsiflexion present
Sacral	Foot plantarflexion present
AMBULATORY PHENOTYPE OR MOBILITY STATUS	
PHENOTYPE	**DEFINITION**
Perfect ambulator	Walk, run, jump indoors and outdoors for all activities without assistance.
Community ambulators	Walk indoors and outdoors for most activities, may need crutches/braces/walker. May use wheelchair for long trips out in the community.

Household ambulators	Walk indoors only with crutches/braces/walker. Get in and out of chair with little assistance. Wheelchair for some indoor activities at home, school, and for all activities in the community.
Nonfunctional ambulators	Walking only in therapy sessions. Wheelchair at all other times.
Nonambulators	Wheelchair bound at all times. Able to transfer from chair to bed.

[a] 2 years of age and older.

Deep tendon reflexes, gait, perineal/anal sensation, and rectal tone should be assessed. The anocutaneous reflex (i.e., “anal wink”) is present when stroking the anus and causes involuntary contraction of the external anal sphincter (Sanders et al., 2002). The bulbocavernosus or Osinski reflex can be assessed by seeing contraction of the external anal sphincter in response to squeezing the glans penis or clitoris (Vodušek and Deletis, 2002). Absence of either of these reflexes indicates interruption of the sacral reflex arcs (S2–S4), which also control bowel and bladder function.

The spine should be visualized and palpated to rule out occult neurologic issues that might arise with bony vertebral or sacral abnormalities. In the vast majority of cases, this examination will reveal a normal spine with an unremarkable, symmetric gluteal cleft. Kriss et al. found that 4.8% of healthy neonates had midline skin stigmata that were referred for further workup, with 7.7% of these (or only 0.4% of the population) having an occult lesion of the spine (Kriss and Desai, 1998). No patient with a simple dimple overlying the sacrum was found to have spinal dysraphism in this study.

Deviations like those shown in Fig. 28.5 require further investigation. Importantly, various cutaneous findings have different predictive value of occult spinal dysraphism (Ben-Sira et al., 2009). Skin changes can range from a sacral dimple <2.5 cm from the anus (low risk) to an abnormal-appearing gluteal cleft or a dermal sinus tract to a vascular malformation (high-risk). **Presence of a lipoma, mass, or hair tuft overlying the spine or sacrum should also be investigated as these confer high risk for occult spinal dysraphism or tethered cord (Guggisberg et al. 2004).** Cases with multiple skin stigmata or findings consistent with VACTERL syndrome are also stratified as high risk. Ultrasonography has been advocated for improved cost and avoidance of general anesthesia sometimes required for MRI. Ultrasonography of the spine may be appropriate for patients up to 6 months of age (ossification of the spine occurs by 10 to 12 months of age) for low-risk lesions, understanding that ultrasonography has been reported to have decreased sensitivity (50% to 70%) (Scheible et al., 1983; Hughes et al., 2003; Drolet and Boudreau, 2004). High-risk lesions, however, should be evaluated with MRI of the lumbar and sacral spine (Ben-Sira et al., 2009).

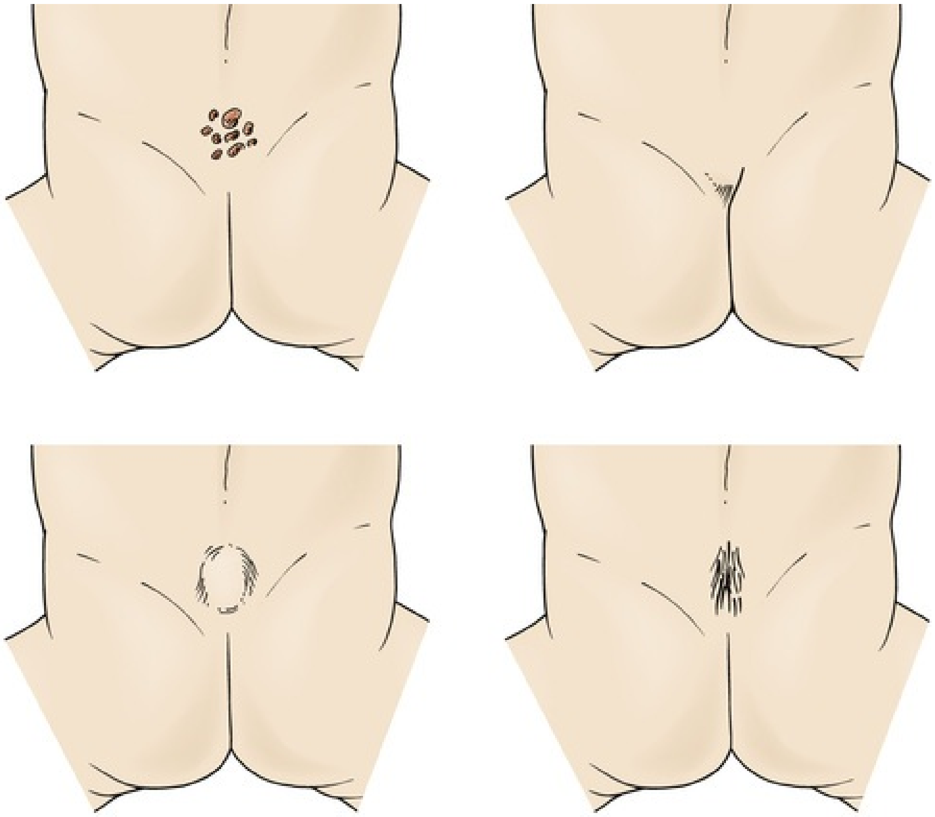

FIG. 28.5 Skin changes over the spine that are suspicious for spina bifida, including isolated macules, deviated cleft, protuberance or mass, or isolated tuft of hair.

Abdominal Examination

Abdominal exam should begin with visual inspection to note the presence of asymmetry or distention, which may indicate bowel gas, fecal retention, or underlying bowel dysfunction. Palpation of all four quadrants should be performed to uncover the presence of enlarged kidneys or bladder, abdominal masses, or palpable stool in the colon. Stool is typically only felt in patients with extreme cases of constipation and may be more appreciable in small children. Tenderness to palpation and/or fullness of the suprapubic area may indicate urinary retention or a full bladder.

Genital Examination

Genitourinary examination should include inspection of the genitalia, looking for evidence of damp underwear or external genital irritation, which can occur with incontinence.

In the male patient, the penis should be inspected and examined. The provider should note the patient's circumcision status. Any erythema, swelling, or tenderness of the prepuce should be documented as possible evidence of balanitis. If circumcised, meatal stenosis should be noted if present. Meatal stenosis only occurs in circumcised males, secondary to irritation of the exposed meatus that induces epithelialization to create a ventral web. **Meatal stenosis is felt to only be relevant if there is significant deviation or narrowing of the stream, and patients and caregivers should be counseled that concurrent symptoms may not necessarily be attributable to this finding or improve with surgical correction.** Inspection of the meatus may be sufficient along with clinical history, but our preference has been to observe the urinary stream directly during voiding to note stream caliber and direction.

In the female patient, the introitus should be examined for pooling of urine or ongoing signs of inflammation (erythema, swelling). Labial fusion is common, particularly in children younger than 2 years of age who are still in diapers (Farage and Maibach, 2005). It rarely causes bladder outlet obstruction and can be treated conservatively. It will usually resolve spontaneously with time by the time of puberty as increased circulating estrogens change the vaginal epithelium (Williams et al., 1986). In some cases, labial fusion can result in pooling of the urine, which may result in urinary stasis and bacterial colonization, thus increasing the probability of developing a urinary tract infection (Leung and Robson, 1993). In cases in which there is ongoing concern, topical estrogen can be used, but families should be counseled that about 10% of cases will recur. If there is concern for continuous incontinence, the vaginal introitus should be examined for an ectopic ureteral orifice. Deformities of the urethral meatus, typically a ventral meatal web, have previously been associated with lower urinary tract dysfunction. Hoebeke et al. described the findings of meatal anomalies in 88 of 288 girls referred for urodynamic study and noted that meatal anomalies were associated with increased likelihood of voiding dysfunction (Hoebeke et al. 1999). A second study by Klijn et al. found a similar association (Klijn et al., 2012). Although previously there was more enthusiasm within the pediatric urology community to surgically intervene in female patients with urethral anomalies, there is only minimal evidence to support such an intervention, underscored by the finding by Klijn that not all meatal anomalies are associated with urinary symptoms.

Key Points

- History and physical examination should be performed to ascertain whether the patient has primarily a storage or emptying disorder. Further workup and treatment is then tailored as needed.
- The important components of a complete history should include symptomatology, voiding frequency, bowel function, prior urinary tract infections, relevant family history, maternal prenatal history including screening ultrasonography, birth history, developmental milestones including toilet training, neuropsychiatric conditions, past medical and surgical history, social history, diet, and review of systems.
- Seven-day bowel and bladder diaries and 48-hour frequency volume charts are invaluable in diagnosing simple and complex lower urinary tract voiding dysfunction.
- Validated questionnaires can be used to assess symptoms (DVSS, DVISS, ISI-P), quality of life (PinQ), and behavioral changes in response to underlying urinary dysfunction (CBCL, SSIPPE).
- Particular attention should be paid to the lower back on physical examination with both visual inspection (examine for dimples, deviations of the gluteal cleft, hair tufts, dermal sinuses, and vascular malformations) and palpation (presence of sacrum, rule out mass).

Laboratory Testing

Urinalysis

Dipstick urinalysis is readily available in most outpatient urology practices. Importantly, urinalysis can aid in the detection of glucosuria, proteinuria, hematuria, leukocyturia, and bacteriuria. Glucosuria occurs in response to prolonged periods of elevated blood glucose in diabetes and may result in polyuria. Proteinuria might be found in isolation on urinalysis. For this reason, urinalysis testing should be repeated at a separate occasion, or 24-hour urine collection with quantification of urine protein may be performed if intrinsic renal disease is suspected. Presence of white blood cells (on dipstick analysis or by microscopy) indicates inflammation or possible infection. Microscopic hematuria is common in the setting of infection, but may also be found in isolation in patients with bowel and bladder dysfunction. Asymptomatic microscopic hematuria in children rarely requires further workup. **Urinalysis with or without urine culture should be performed if there are irritative voiding symptoms (dysuria, urgency, or frequency) to rule out untreated urinary tract infection.**

Markers on urinalysis for infection (leukocyte esterase, nitrite, white blood cells, and/or bacteria on microscopy) should be interpreted within the clinical context of patient symptoms. Urinalysis is a low-cost, easy-to-implement screening tool, and negative urinalysis in a patient who presents with lower urinary tract symptoms is reassuring. In cases with a suspicious urinalysis, confirmatory testing with urine culture and/or institution of empiric antibiotic therapy is indicated.

Urine Culture

We do not recommend testing all patients with disordered lower urinary tracts with urine culture, as this will lead to overtesting, false positives and overtreatment, particularly in patients who are colonized with bacteria. Patients who perform clean, intermittent self-catheterization are at high risk for bacterial colonization of the bladder, and urine culture should be reserved for those patients with a high pretest probability of symptomatic urinary tract infection (fever, abdominal or suprapubic pain, malaise, new-onset urinary incontinence or worsened incontinence, new or worsened bladder spasm). Malodorous urine often invites the question as to whether a child is silently harboring a urinary tract infection. In a study by Struthers et al., 110 patients underwent urinalysis and culture as part of admission for unwell or febrile children not specifically suspected of having a urinary tract infection, and there was no correlation between parental concerns of malodorous urine and positive urine culture (Struthers et al., 2003). Another study by Gauthier et al. similarly asked 331 parents in the emergency department with their child about smelly urine in the context of suspected urinary tract infection and found a small association between the two (adjusted odds ratio [AOR] 2.73, 95% CI, 1.46 to 5.08) (Gauthier et al., 2012). **By itself, the presence of malodorous urine does not have enough sensitivity or specificity to definitively rule in or rule out testing.**

These two results are not necessarily in conflict, as they were performed under conditions with different pretest probabilities for urinary tract infection. We recommend to parents and patients with isolated malodorous urine in the absence of other signs or symptoms of urinary tract infection to increase hydration so as to alter the specific gravity of the urine and dilute volatile compounds. This avoids further testing in most cases and subsequent overtreatment, which fosters antibiotic-resistant organisms. Overtreatment can compound the difficulty in treating patients who develop true symptomatic, recurrent urinary tract infections.

Additional Testing

Blood samples are rarely indicated in the typical workup of lower urinary tract dysfunction, unless the history, physical examination, or other testing reveals possible underlying kidney disease or risk factors for the development of kidney disease. For example, proteinuria on repeat urinalysis should prompt serum creatinine testing and/or 24-hour urine collection to quantitate total protein content of the urine.

Key Points

- Children presenting with lower urinary tract symptoms should have urinalysis testing, with important test details including specific gravity, protein, and glucose, and the presence of white blood cells, red blood cells, or bacteria.

- Isolated malodorous urine in the general population lacks sensitivity and specificity to detect positive urine culture in an otherwise asymptomatic patient.
- Blood testing is not recommended unless there are specific concerns for concomitant upper tract disease.

Urodynamic Evaluation

Urodynamic testing, whether through noninvasive tests like uroflowmetry, pelvic ultrasonography, or patch EMG or invasive tests like formal cystometry requires a common, standardized language from which accurate descriptors of test results can be drawn. In 2014, the ICCS published an update to the previous 2006 report on standardized terminology of lower urinary tract function (Nørgaard et al., 1998; Nevéus et al., 2006; Austin et al., 2014). This important document codifies language to describe results of tests in common terms, thus allowing researchers and clinicians to compare studies and results on a comparable basis, avoiding ambiguous older verbiage. **We highly recommend that all clinicians who treat patients with lower urinary tract dysfunction read this important paper.**

Noninvasive Testing

Uroflowmetry

Uroflow studies measure the flow of urine during urination. They are performed by having the child void into a special toilet or device that measures volume per time (Fig. 28.6A). This study is readily available in most urologists' offices and providers for a number of different objective measures, including voided volume, void pattern, and maximum (Qmax) and average (Qavg) urinary flow rates. **The most important variables obtained by the uroflow are voided volume, Qmax, and void pattern** (Van De Beek et al., 1997). Uroflowmetry may be performed concomitantly with electromyography (EMG) testing of the pelvic floor musculature and external urethral sphincter by affixing pads to the perineum.

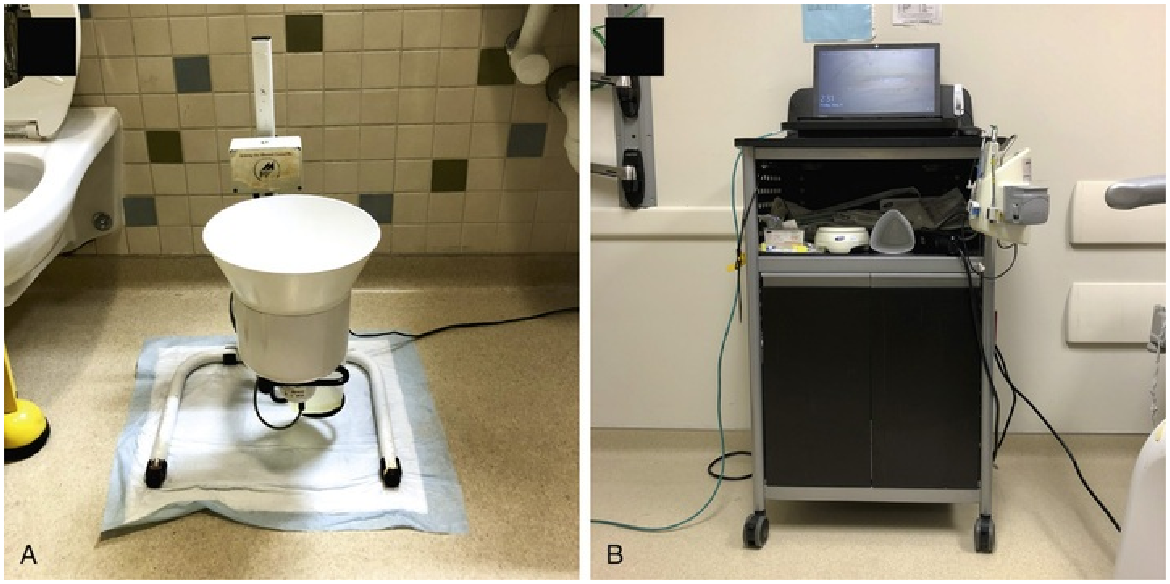

FIG. 28.6 (A) Uroflowmetry test equipment. (B) Urodynamic testing setup with computer and pressure transducer.

As noted earlier, the ICCS developed standardized terminology and definitions for uroflowmetry reporting, describing specific types of urine flow patterns (Fig. 28.7). These are not absolute, but they do provide a guide to possible underlying etiologies of lower urinary tract dysfunction.

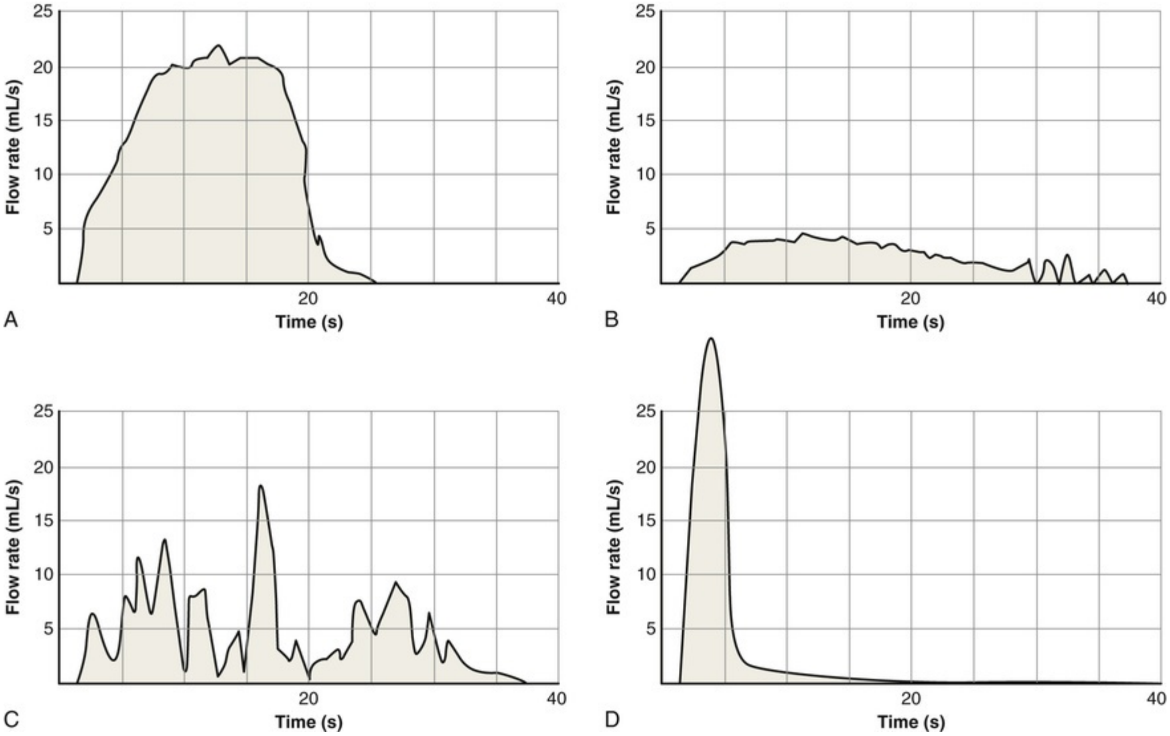

FIG. 28.7 (A) Example of uroflowmetry printout for a normal patient with a bell-shaped curve. Total volume is usually recorded, and a minimum of ~50 to 100 mL is needed to qualitatively assess urine flow pattern. (B) Obstructive flow pattern. (C) Overactivity pattern that resembles staccato or flow starting and stopping. (D) Peaked flow pattern with rapid emptying of the bladder, which may cause turbulence and possible symptoms during urination.

Bell-Shaped Curve.

A healthy child of any age, sex, race, or voided volume should result in a bell-shaped curve.

Tower-Shaped Curve.

A high-amplitude, peaked curve of short duration suggests an overactive bladder with sudden detrusor contraction. Not all children with overactive bladder, however, present with this voiding phenotype.

Staccato-Shaped Curve.

This flow pattern is irregular and fluctuates but does not reach zero flow during voiding. Intermittent sphincter overactivity is suggested to be the underlying cause and is felt to be associated with bowel and bladder dysfunction.

Interrupted-Shaped Curve.

Like the staccato curve, the interrupted shape uroflow result is also irregular, but there are segments of the curve that read zero flow, indicating cessation of urination and inadequate detrusor contraction (as in underactive bladder with Valsalva voiding). Between abdominal strains to void, the flow of urine ceases. Another possible explanation is detrusor-sphincter dyssynergia (DSD), in which the external sphincter does not relax appropriately with detrusor contraction. Uroflow testing with EMG can determine whether this is the case.

Plateau-Shaped Curve.

This uroflow result is a flat, low-amplitude prolonged flow curve that is suggestive of downstream obstruction (bladder outlet, posterior urethral valves, urethral stricture). This curve type may also be seen in patients with underactive bladder, whereby a continuous, low-amplitude pressure either from the detrusor or Valsalva generates force to expel urine.

Further Standardization.

Qmax is considered the most relevant variable of a uroflow measurement. Peaks may be artifactual, so Qmax should be only be registered when the peak lasts at least 2 seconds (Szabo and Fegyverneki, 1995). Multiple attempts have been made to find objective, quantifiable methods to normalize uroflow results to allow better comparisons between different patients (Chang and Yang, 2008; Kanematsu et al., 2010; Vijverberg et al., 2011; Gupta et al., 2013; Yang et al., 2014). Some of these efforts were suboptimal or based on populations that lacked generalizability. Recently, Franco et al reported on a method to overcome prior issues, including using a large healthy, asymptomatic patient group of varied ages to define normal and abnormal (Franco et al., 2016). His group also corrected for total bladder capacity (voided volume + PVR), understanding that flow rates naturally diminish with underdistention and overdistention of the bladder. Finally, the authors normalized actual flow results to an expected result, which provides for a single number or index by which to judge and classify the result. In this study, 1268 healthy children who were presumed normal voiders were used to create quadratic equations using nonlinear regression for each sex. A flow index was calculated for each patient, and ROC analysis was performed to predict flow pattern. Second voids for each patient were used to verify the resulting predicted flow patterns of either plateau, bell-shaped, or tower in configuration. Specificity to detect each of the predominant flow patterns was high (83% to 97% for males, 66% to 86% for females). Staccato and interrupted patterns (see later) were not classifiable because of irregular flow patterns, and the authors suggest that the ICCS update uroflow nomenclature to make *staccato, interrupted*, and *smooth* each a subtype of the three primary patterns. Table 28.3 provides the necessary equations to calculate the estimated Qmax, the Qmax flow index (FI), and finally the reference ranges to classify each curve as either plateau, bell-shaped, or tower. Voided volumes greater than 50 mL are required to have an interpretable result.

TABLE 28.3

Calculation of Estimated Qmax, Qmax Flow Index,[a] and Reference Ranges to Determine Flow Types

	QUADRATIC EQUATIONS	DERIVATION OF QMAX FI	QMAX FI RANGES FOR CLASSIFICATION		
	ESTIMATED QMAX		PLATEAU	BELL-	TOWER

				SHAPED	
Male	$11.26 + 0.0701(\text{TBC}) - 0.0000513(\text{TBC}^2)$	Actual Qmax/Estimated Qmax	≤0.70	0.71–1.25	>1.25
Female	$10.723 + 0.073(\text{TBC}) - 0.0000423(\text{TBC}^2)$		≤0.68	0.69–1.10	>1.10

[a] Flow index is actual Qmax divided by estimated Qmax.

FI, Flow index.

There are a few caveats that should be mentioned. (1) To obtain an interpretable uroflow, the child must be toilet trained; (2) uroflowmetry only provides information during the elimination phase, not the storage phase; and (3) when voided volume is less than 50% of expected bladder capacity (EBC) for age, the result may not be valid (Austin et al., 2014), although the flow index is valid down to 50 mL (Franco et al., 2016). Finally, it is critical to obtain more than one curve to improve the accuracy, reliability, and interpretation of the test.

Pelvic Ultrasonography

Ultrasonography in children has become a mainstay of diagnosis and workup of voiding dysfunction. It can be particularly useful either as a formal radiology-performed examination (renal and bladder ultrasonography) or in the clinic (prevoid and postvoid pelvic ultrasonography). In patients with non-neurogenic and neurogenic lower urinary tract dysfunction, ultrasonography can be a useful tool to determine which patients might benefit from invasive testing (formal urodynamics). By measuring bladder volumes and wall thicknesses in children with voiding dysfunction, nocturnal enuresis (Yeung et al., 2004), and recurrent urinary tract infections (Yeung et al., 2007), clinicians can predict which children are more likely to have pathology on urodynamics. In children with spina bifida, thickness of the bladder wall has been correlated with higher bladder pressures and decreased compliance on urodynamics, which puts the upper urinary tract at risk for deterioration (Tanaka et al., 2008).

Prevoid and postvoid ultrasonography of the pelvis is quick, painless, and can usually be done in the urology clinic if an adequate machine is available. This allows for a noninvasive and nonionizing method to visualize the bladder and rectum. Relevant measurements are discussed in the following sections.

Bladder Wall Thickness.

Pelvic ultrasonography may show thickened bladder wall (>**5 mm thick when**

empty or >3 mm thick when full) indicating increased detrusor workload during emptying (Fig. 28.8A) (Jequier and Rousseau, 1987). **Measurement can be performed with the bladder empty or full, and wall thickness inversely varies with fullness of the bladder.** Increased wall thickness has been associated with voiding dysfunction, DO, and increased activation of the pelvic floor musculature (Charalampous et al., 2013).

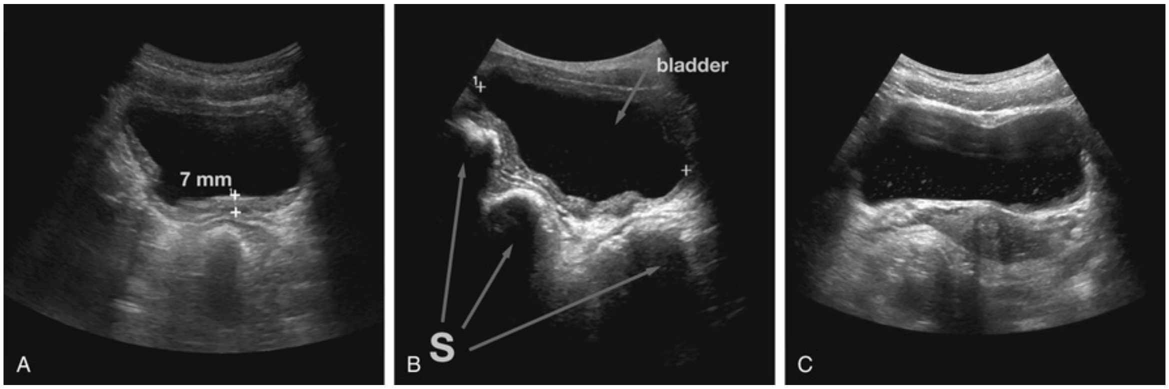

FIG. 28.8 (A) Thickened bladder wall. (B) Large stool balls posterior to the bladder denoted by *'S'* seen in rectum that are distorting the shape of the bladder. These are prominent and visible on pelvic ultrasound. (C) Mobile debris visible within the bladder on pelvic ultrasound.

Yeung et al. reported on bladder ultrasound findings and their correlation to urodynamic findings and treatment outcomes in 514 patients with nocturnal enuresis as compared with 339 healthy age-matched controls (Yeung et al., 2004). Specifically, they measured the bladder volume wall index (BVWI, ratio of bladder volume to wall, normalized to expected, expressed as a percentage) and found that normal BVWI was highly predictive of normal voiding function. Interestingly, the authors found that patients with nocturnal enuresis and normal BVWI had better response to desmopressin therapy than those with abnormal BVWI (<70% = thick-walled, small-capacity bladder or >130% = thin-walled, high-capacity bladder).

Postvoid Residual.

Postvoid residual (PVR) is any urine remaining in the bladder after voiding (or self-catheterization). It is typically calculated from measurements in neurologically intact children. Obtained values can be highly variable from measurement to measurement in the same individual and is adversely affected by bladder overdistention (Chang and Yang, 2008; Yang and Chang, 2008). Chang and Yang suggested that abnormal PVR urine volume should be defined as low as PVR greater than 20 mL on repeat micturitions without bladder overdistention (Chang et al., 2013). In a study of 1128 healthy Taiwanese children between 4 and 12 years of age with a bell-shaped uroflow pattern and a voided volume greater than 50 mL, age-specific cutoffs for normal PVRs were determined. For children 4 to 6 years of age, a single PVR greater than 30 mL or greater than 21% of functional bladder capacity (voided volume + PVR) as a percentage of EBC was deemed abnormal. For children 7 to 12 years of age, a single PVR greater than 20 mL or 15% of EBC was considered elevated.

To be considered a valid measurement of PVR, normative conditions must have been present: the bladder should not be underdistended (<50% EBC) nor overdistended (>115% EBC); PVR should be obtained immediately after voiding (<5 minutes).

Rectal Diameter.

As the rectum is situated behind the bladder, it is typically seen on pelvic ultrasonography. Patients with functional constipation may show a large stercoral bolus (stool ball, see **Fig. 28.8B**) in the rectum, which should be correlated with clinical findings. **Rectal diameter greater than 30 mm in a child without the urge to defecate is suggestive of bowel dysfunction, though rectal diameter alone may not be entirely predictive** (Joensson et al. 2008; M. Y. Berger et al., 2012).

Urinary Debris.

Debris on ultrasonography usually indicates urinary stasis, but it also raises the question as to its relation to possible underlying infection (see Fig. 28.8C). McQuaid et al. studied 3995 patients presenting for voiding cystourethrogram and renal bladder ultrasonography on the same day, for which urine culture was part of the preimaging protocol (McQuaid et al. 2017). In this study, 34 patients with debris were matched to 155 controls, and the authors found a significant correlation on conditional logistic regression between positive urine culture and presence of debris (odds ratio 7.88, 95% CI, 1.88 to 33.04, $P = 0.0048$). Primary limitation of this study is its generalizability given the screening nature of the urine culture in presumably asymptomatic patients. Stevenson et al examined their institutional database for a similar cohort of 445 patients with imaging and urine culture, noting that 20% of patients had a positive urine culture and 22% had debris on imaging (Stevenson et al., 2018). Although the rates differ slightly from the prior study, they found a similarly elevated risk for positive infection in the setting of debris on ultrasonography (relative risk 3.90, 95% CI, 2.73 to 5.55). The authors calculated the sensitivity and specificity for bladder debris to detect a positive urine culture was 52% and 86%, respectively.

Future.

Ultrasonography has the potential to also perform other measurements, such as to assess the viscoelastic properties of the detrusor wall and use this as a correlate to bladder compliance, which is typically measured invasively during formal urodynamics. Nenadic et al. showed proof of principle for this with an ex-vivo model and in-vivo vibrometry measurements in three healthy controls and two patients with neurogenic bladder undergoing simultaneous urodynamics (Nenadic et al., 2016). Compliance measures had high correlation with noninvasive ultrasound bladder vibrometry measurements.

Patch Electromyography

Electromyography (EMG) is typically performed in conjunction with uroflowmetry, but is not routinely used in all urology practices. **EMG, when positioned on the perineum or near the anal sphincter, provides electrical potentials of the pelvic floor musculature, which should become quiescent during voiding** (Fig. 28.9). Lag time is the time from the start of pelvic floor relaxation at the beginning of voiding effort to the start of urine flow. Lag times for children with a full bladder typically range from 2 to 6 seconds (Van Batavia et al., 2011). Shorter lag times less than 2 seconds are associated with DO and symptoms of urgency/frequency (Combs et al., 2013; Van Batavia et al., 2014). Prolonged lag times greater than 6 seconds are associated with primary bladder neck dysfunction (Combs et al., 2005). **The addition of EMG to the urologist's armamentarium allows for greater appreciation of coordination between pelvic floor musculature, sphincteric relaxation, and bladder emptying, thus providing for a noninvasive method to denote synergistic or dysynergic voiding patterns**.

Other Measures

Functional bladder capacity (sometimes referred to as total bladder capacity) is defined as the working, day-to-day capacity of the urinary bladder. It can be obtained a number of ways, including largest volume recorded on voiding diary or by taking voided volume on uroflowmetry plus PVR. Normal cutoffs vary, but typically 70% to 115% (or 130% in some studies) of EBC is considered the normal range (Rushton et al., 1996; Yang and Chang, 2008; Yeung et al., 2004).

Key Points

- Noninvasive urodynamics includes modalities like uroflowmetry, patch electromyography, and pelvic ultrasonography.
- Uroflowmetry provides useful information regarding flow characteristics

during urination, including shape or pattern. Qmax is the most relevant quantitative variable when assessing bladder outflow.

- Ultrasonography is another useful adjunct, noninvasive examination that can provide a number of different clinically important variables, including prevoid and postvoid bladder volumes to calculate PVR, bladder wall thickness, rectal diameter, and presence of debris.
- Electromyography provides for assessing coordination between the bladder and external sphincter to determine whether voiding is synergistic or dyssynergia and can also be used in conjunction with uroflowmetry to determine the lag time.

Formal Urodynamics

Urodynamics in children is not too dissimilar to adult patients, in that it allows for objective information regarding bladder-filling dynamics; bladder compliance; presence of vesicoureteral reflux; other congenital bladder, bladder neck, or urethral anomalies (when performed with fluoroscopy); bladder capacity; bladder pressures; detrusor-sphincter dyssynergia; DO; and PVR. There are no formal recommendations for when urodynamics are indicated in children, and practice patterns vary considerably in the application and routine use of urodynamics to screen, diagnose, and follow various pediatric patient populations. **In patients with known lower urinary tract dysfunction secondary to a congenital or acquired neurologic deficit or caused by severe obstructive uropathy, formal urodynamic studies establish bladder pressures. Similarly, patients with pathologies that might result in neurogenic bladder—particularly those with new-onset lower urinary tract symptoms—should also be thoroughly investigated so as to verify bladder function.**

Common pediatric conditions known to result in neurogenic bladder include spinal dysraphism, sacrococcygeal teratoma, sacral agenesis, transverse myelitis, and spinal cord injury. Lower urinary tract dysfunction also commonly results from severe obstructive processes, such as posterior urethral valves, urethral atresia, or large ectopic ureteroceles. **Studies of pediatric patients with lower urinary tract symptoms in the absence of neuropathy have examined the utility of routine invasive urodynamics and found that significant information was rarely obtained to justify testing** (Hoebeke et al., 2001, Soygur et al., 2004, Kaufman et al., 2006). Studies may be obtained for baseline or surveillance measurements in patients with known disease, may be repeated to reestablish baseline measures before medical or surgical therapies, or may be done to rule in or rule out neurogenic bladder. Many congenital conditions affecting lower urinary tract function result in altered function over time, potentially necessitating repeat urodynamic study (De Gennaro et al., 1998; De Gennaro et al., 2001; Koff et al., 2002). Similarly, providers may opt to repeat studies after implementation of a new medical or surgical therapy to reestablish filling pressures and determine other important urodynamic parameters. **Generally, formal urodynamic testing should be reserved for patients in whom a new or abnormal result will affect treatment options.** Here, we cover some unique considerations in pediatric patients.

Unique Considerations in Pediatric Patients

Knowledgeable and professional staff are critical to successful urodynamic testing in children, who require a “kind, understanding and relaxed atmosphere” (Hjälmås, 1988). Oftentimes, patients will have already had invasive studies or urodynamics testing and will arrive to their appointment with anxiety. Parents should be allowed in the room throughout the study. Television, video games, or interactive tablets can serve as a useful distraction (Drzewiecki and Bauer, 2011). Standardization of the technique is paramount for efficiency and adequate interpretation of results across studies, and Spinoit et al. recently published a short protocol with video explaining standard urodynamics setup and technique in pediatric patients (Spinoit et al., 2016). A typical machine is shown in Fig. 28.6B.

To this end, however, there are still some areas of controversy and variation in practice that are less well defined. One area includes the need for routine urinalysis, urine culture, and/or prophylactic antibiotics before ambulatory urodynamic testing. A large, retrospective review of a single institution in which urine cultures were routinely performed before urodynamic testing demonstrated that there was an increased likelihood of bacteruria in patients with known risk factors (e.g., patients who perform clean intermittent catheterization) (Snow-Lisy et al., 2017). Posturodynamics infection was diagnosed in only 1.4% of patients, although this was in the setting of 21% of patients having received either prophylactic or treatment antibiotics before the test. Risk factors for postprocedure infection included performing intermittent or overnight catheterization, recent clinically diagnosed urinary tract infection, immunosuppression, or symptoms on the day of the procedure. The authors called into question the need for routine urine cultures given the low clinical yield, even in spite of a high rate of bacteruria in that patient population undergoing urodynamics.

A similar study of patients undergoing voiding cystourethrogram showed that the risk for postcystogram infection was about 1% (Johnson et al., 2017). In this study, 50% of patients were taking antibiotics at the time of the test, but counterintuitively, of the 12 patients who developed infection, 11 were taking antibiotics before and up to the procedure. Given the rarity of infection, the study suggests a large proportion of patients were unnecessarily treated.

Finally, a quality improvement initiative was started at another center to selectively identify patients appropriate for screening urinalysis on the basis of symptoms before voiding cystogram (Mouton et al., 2017). Out of 266 urodynamic studies, only 3 met criteria for urinalysis, of which 2 were positive. One test was performed, and the other was rescheduled. **Taken together, routine screening or antibiotic prophylaxis for urinary tract infection before urodynamics in all patients likely constitutes overtreatment.** Select patients with risk factors might benefit from screening, prophylaxis, or empiric treatment, but the data here are also weak. New lower urinary tract symptoms on the day of or leading up to the procedure may prove to be the most rational approach to selective screening for infection before urodynamics, which is a fairly low-risk procedure for subsequent urinary tract infection.

Sedation either for catheter placement or the entire procedure may create concerns about the effects on urodynamic parameters (Sweeney et al., 2008). Urodynamics studies aim to simulate bladder function and compliance. Sedation may alter the bladder's function through altered neurologic pathways or direct pharmaceutical effect on the detrusor muscle. For these reasons, general anesthesia is not recommended, and sedation should be avoided (Wen et al., 2000). Several studies have demonstrated a reduction in detrusor contractions in animal models (Ha et al., 1993; Schaufele et al., 1995). When sedation is required, it may only be needed for insertion of the urodynamic catheters, which can be done in advance of the study. For sedation during cystometry, ketamine may provide some benefits over mizadolam in onset and recovery time and improved effect (Thevaraja et al., 2013). Safety may be improved with ketamine as well over other common sedatives (Bhatt et al., 2017). Bozkurt et al. performed the only study to examine urodynamic results in the same patients with and without sedation (Bozkurt et al., 1996). No significant changes were noted in any urodynamic parameters, although this remained a small sample size and has not been repeated.

The patient should empty the bladder before the study, or urine can be emptied with catheter placement for the bladder instillation. Sitting versus supine positions do not appear to affect measurements (Lorenzo et al., 2007). Lidocaine jelly is used to aid insertion of multichannel or microtranducer pressure catheters into the bladder and rectum, reducing pain and discomfort (Gerard et al., 2003). The smallest-size catheter should be used, typically 6 Fr dual-lumen disposable catheters (Schäfer et al., 2002). For patients with a vesicostomy, a Foley catheter with the balloon inflated can be put on small amount of tension to occlude the bladder. For patients with a catheterizable urinary channel without bladder neck closure, pressure catheters may be placed either through the channel or through the native urethra. Similarly, patients with a colostomy can have the catheter to measure abdominal pressures (P_{abd}) placed in the colostomy as opposed to the rectum (if present). In female patients, the abdominal catheter may be placed in the vagina for comparable results to measure P_{abd} (Schäfer et al, 2002). Patch electrodes are placed symmetrically on the perineum in the 3 and 9 o'clock positions left and right of the anus for electromyography. Patches should be secure to the skin to ensure adequate conductivity. This may be obtained by using alcohol preparation pads and fine abrasive paper before application. EMG was originally described with bipolar perianal muscle needle electrodes; however, these are no longer recommended in children as needle placement causes pain and anxiety, and surface electrodes have been shown to produce similar, accurate results (de Jong and Klijn, 2009; Maizels and Furlit, 1979). Urodynamic systems should be capable of sampling greater than 1000 Hz to allow for accurate clinical discrimination between movement artifact and true sphincter activity (de Jong and Klijn, 2009).

Ambulatory urodynamic monitoring or natural fill cystometry offers an alternative to traditional cystometry with the benefit of natural, physiologic diuresis to fill the bladder and a more natural environment with minimization of Hawthorne effect and physiologic stress but the potential downside of increased time, increased effort, and lack of standardized pediatric protocols and experience (De Gennaro et al., 2008). In one study, 29 infants and young children with a mean age of 3.9 years underwent natural-fill cystometry via a suprapubically placed 6-Fr dual-lumen catheter in the bladder and a 5-Fr vented balloon-tip catheter placed in the rectum 24 hours before testing (Yeung, 1998). In this study, 14 patients underwent conventional study for comparison and demonstrated significant differences in bladder capacity (69.5 vs. 91.6 mL, $P <$

0.02), change in Pdet during filling (8.4 vs. 12.7 cm H_2O, P <0.01), and maximum recorded pressure during micturition (112.8 vs. 89.3 cm H_2O, P <0.01). Another study of healthy children and adult patients demonstrated similar findings that ambulatory testing resulted in lower voided volumes, smaller changes in Pdet during filling, and higher voiding pressures as compared with conventional testing (Robertson et al., 1994).

Unlike adult patients, urodynamics in the pediatric setting must account for a wide variation in estimated bladder capacities, from newborns (30 to 50 mL) to young adults (400 to 500 mL). This is important because urodynamics parameters can be affected by the fill rate, particularly if it is too fast, thus producing artifactual results. Hjalmas noted that **a fill rate of 5% to 10% of EBC per minute appears ideal** (Hjälmås 1988). Saline or contrast medium should not be cold, and rather should be between room temperature and body temperature (Goodman et al., 2003). A randomized controlled trial of room temperature vs body temperature infusate was performed in 91 pediatric patients undergoing urodynamics (Chin-Peuckert et al., 2004). Each patient underwent two filling cycles with order of the infusate randomly selected. No differences were seen in leak point pressures, voiding pressures, or PVR. Room-temperature saline demonstrated higher bladder capacity, and higher pressure at maximum capacity than body-temperature saline, but these differences, although significant, were not felt to be clinically significant. Filling should be stopped when the patient expresses a strong urge to void, discomfort is present, micturition occurs, leakage is greater than the fill rate, detrusor pressures exceed 40 cm H_2O consistently, or the instilled volume has exceeded 150% of the expected capacity (Drzewiecki and Bauer, 2011). Repeat filling cycles in a single setting may be performed with the same or slower fill rate to confirm findings. Prior editions of the International Children's Continence Society guidelines for urodynamic terminology and testing made formal recommendations for two or more filling cycles, but the most recent guidelines (as of 2015) note this can be done at the discretion of the provider (Nørgaard et al., 1998; Bauer et al., 2015). In a study of 70 patients with DO and 42 patients with normal urodynamic parameters, maximum filling pressures and number of contractions varied significantly across three repeated filling cycles on formal urodynamics, with pressures decreasing between the first and third cycle and number of contractions decreasing in subsequent cycles compared with the first (Sözübir et al., 2005). Repeat cycles may prolong the test and lead to further anxiety. Providers should consider the marginal benefit of repeat filling cycles against the information obtained by the first run.

Adding fluoroscopic imaging capabilities to urodynamics is referred to as *video urodynamics*. It requires that a radiopaque contrast agent be used in place of saline for instillation into the bladder. If the capability exists, this technique can increase diagnostic specificity and add more useful information about bladder shape and trabeculations, presence of vesicoureteral reflux or bladder diverticula, and configuration of the bladder neck (open vs. closed) (Glazier et al. 1998). Timing of events like reflux or incontinence can be correlated with visual cues about bladder fullness.

Interpretation of Studies

Interpretation of urodynamics should be done by a trained pediatric urologist, advanced practice provider, or urodynamicist. Intrarater and interrater reliability of interpretation of individual, objective urodynamics parameters was found to be generally good to excellent (intraclass correlation coefficient ranging from 0.74 to 0.99) in an adult multicenter study (Zimmern et al., 2006). Although objective parameters may be largely measured similarly between practitioners, subjective interpretation of pediatric urodynamics shows much poorer agreement (Venhola et al., 2003). Attempts to improve the interpretation through a grading scheme or standardization have been made (MacNeily et al., 2007). Despite these efforts, interpretation of pediatric urodynamic studies remains fairly subjective, even among peers who trained together (Dudley et al. 2017).

Formal urodynamic testing encompasses the storage and voiding phases. During the storage phase, several important parameters are reported, including Pves, Pabd, and Pdet. Pves and Pabd are the reported pressures from the bladder and rectal catheters, respectively. These should be “zeroed” at the beginning of the examination with respect to atmospheric pressure and the height of the pubic symphysis. Pdet is determined by subtracting Pabd from Pves (Pdet = Pves – Pabd). Pdet corresponds to the inferred pressure generated by the detrusor muscle. During normal filling, P_{det} should remain flat without any changes during cough, laugh, or Valsalva. Peaks (rise and fall) in detrusor pressure during filling corresponds to DO. This can be further divided into neuropathic and idiopathic DO, depending on whether neuropathology is present or not. Providers interpreting urodynamics should verify that there was no provocative action that resulted in DO such as cough or Valsalva. These contractions may not be sensed by patients in many cases. In patients with normal sphincteric function, detrusor contractions during filling are usually accompanied by increased contraction of the pelvic floor and external sphincter to guard against leakage, and this can be noted on the EMG strip. Detrusor underactivity is not readily apparent from Pdet, but manifests as large bladder capacity, low filling pressure, and no contractions during filling in combination with absence of a sustained detrusor contraction during attempted voiding with inability to empty.

Bladder compliance is a measure the urodynamic provider should calculate for every patient. Compliance equals bladder volume (ΔV in mL) divided by change in pressure ($\Delta Pdet$ in cm H_2O). Compliance generally refers to the bladder's ability to accommodate an increase in volume with a negligible to small increase in pressure. Compliance cannot be inferred from Pdet measures alone, and providers should be aware that small or contracted bladders with low capacity may not exhibit absolute detrusor pressures that are considered dangerous (>30 to 40 cm H_2O), but when compliance is calculated, it may appear abnormal (<20 mL per cm H_2O) (McGuire et al., 1981; Ghobish, 2001). In this situation, the absolute pressure is likely more useful than compliance to demonstrate safe upper tracts despite small capacity. The shape of the Pdet tracing is also important to consider if it is elevated. If it rises early in the study, this suggests early loss of compliance and may portend unfavorable outcomes for the patient as he or she may spend a majority of the day at higher pressures. The provider should also take time to verify that bladder and abdominal leads were appropriately zeroed to avoid missing abnormal compliance or falsely low Pdet readings. Additionally, compliance may not be readily quantified in the setting of marked DO. To minimize variability, the ICCS recommends identifying the most linear portion of the volume-pressure relationship during the study and using this to calculate compliance (Bauer et al., 2015). Ideally, this measure spans the entire filling phase.

Leak point pressures should also be noted if there is incontinence during the filling phase of the cystometrogram. Leak point pressures come in two varieties and should be distinguished from one another: detrusor leak point pressure (DLPP) and abdominal leak point pressure (ALPP). DLPP is noted when there is incontinence in the absence of increased abdominal pressure and no detrusor contraction (Austin et al., 2014). This measure is more commonly used by pediatric urologists as it denotes the pressure at which “pop off” occurs. If this leakage occurs at low pressures (<40 cm H_2O), then the upper urinary tract is considered safe (McGuire et al., 1981; Landau et al., 1994; Tanaka et al., 1999). Patients with high DLPP (>40 cm H_2O) or no DLPP with high pressures (absence of incontinence during study) are at increased risk for damage to the upper tract because these pressures may be transmitted to the upper tracts. McGuire et al. demonstrated this in pediatric patients with myelodysplasia, in whom the authors demonstrated DLPP greater than 40 cm H_2O, resulted in hydronephrosis or secondary vesicoureteral reflux in 85% of patients (McGuire et al., 1981). **The exact “safe” cutoff has not been defined, but most experts agree that 40 cm H_2O should be considered the upper limit and that providers should strive for the lowest pressure that is reasonably achievable** (Rosier et al., 2013). ALPP is noted when there is incontinence secondary to a rise in abdominal pressure (e.g., cough, laugh, Valsalva) in the absence of a detrusor contraction, and it represents the ability of the bladder outlet to resist increases in Pabd (Austin et al., 2014; McGuire et al., 1993). The pressure is traditionally taken from Pves (as opposed to Pdet). Although most emphasis in pediatric urodynamics is on protecting the upper urinary tract, ALPP is purely a measure of outlet function. Normal ranges of ALPP in children are not available. The closest analog are normal ranges in adult females by McGuire et al. (McGuire et al., 1993). ALPP less than 60 cm H_2O reflects intrinsic sphincter deficiency, 60 to 90 cm H_2O denotes equivocal measure with some component of sphincter deficiency, and greater than 90 cm H_2O translates to no deficiency.

Although DLPP and ALPP are both referred to as leak point pressures, they refer to very different characters of lower urinary tract function. DLPP corresponds to an impaired bladder's response to increased detrusor pressure. Lower DLPP (<40 cm H_2O) is considered safe, and higher readings are concerning for increased likelihood of injury to the upper tract. Stated otherwise, an elevated DLPP refers to a bladder in which pressures are too high before the pop-off mechanism of urethral leakage occurs. ALPP measures outlet resistance (bladder neck and sphincter) to increases in abdominal pressure. Low ALPP signifies intrinsic sphincter deficiency.

Maximum bladder capacity should be noted for any study and corresponds to the volume instilled during the study. This measure may be confounded if there is profound incontinence during filling. This measure should be differentiated from estimated bladder capacity (see earlier) and functional bladder capacity. Functional bladder capacity refers to the volume the bladder typically sees during normal routines before emptying. This is best gained through the use of a voiding diary, also discussed earlier. Abnormal bladder capacity exists when either the maximum or functional bladder capacity is abnormally high (>130%

of estimated bladder capacity) or low (<66% of estimated bladder capacity). Unto itself, abnormal bladder capacity is not necessarily concerning, but will often be present with other urologic or urodynamic findings (e.g., large bladder capacity and infrequent emptying or low bladder capacity and increased Pdet and/or loss of compliance).

If the patient is able to void, several important parameters should be noted during the emptying phase. This portion of urodynamics is referred to as a pressure-flow study. It combines uroflowmetry (discussed earlier) with a pressure study, and just as with uroflowmetry, the results are only valid under normative conditions: patient is able to void, there is minimum voided volume of 50 to 100 mL, and voided volume not less than 50% of functional bladder capacity (de Jong and Klijn, 2009). Flow rate (either Qavg or Qmax measured in mL/s) and voiding pattern should be recorded. Pdet at maximum flow is also important to note. The pressure the detrusor generates to facilitate voiding and flow rate are related to urethral resistance. Elevated Pdet and low Qmax may indicate urethral or bladder outlet obstruction. This may be anatomic (e.g., urethral valves or urethral stricture) in which there is appropriate coordination between relaxation of the pelvic floor and urethral sphincter, or functional (detrusor-sphincter dyssynergia [DSD]) in which there is a detrusor contraction without relaxation of the pelvic floor and urethral sphincter. To differentiate between these two conditions, it is necessary to examine the flow curve, Pdet, and EMG leads together. In DSD, the flow is often intermittent or staccato, the Pdet is higher than expected, and EMG readings show increased activity reflecting nonrelaxation. Normal ranges for Pdet at Qmax in children are similar to adults. Average Pdet at Qmax is 66 cm H_2O in boys and 57 cm H_2O in girls (Schmidt et al., 2002, 2004; Defreitas et al., 2004). Healthy newborn and infant males normally have increased voiding pressures in the presence of a urethral catheter used during urodynamics, and Pdet during voiding may be as high as 118 cm H_2O and 75 cm H_2O for these groups, respectively (Sillén, 2004; Yeung et al., 1995). Finally, PVR should be noted.

To summarize, urodynamic findings that increase the level of concern for injury to the upper urinary tract include: (1) impaired compliance (<10 mL per cm H_2O considered severely impaired, 10 to 20 mL per cm H_2O is moderately impaired, >20 mL per cm H_2O is normal); (2) detrusor sphincter dyssynergia (DSD) coupled with poor emptying, inability to void, and/or elevated voiding pressures; (3) sustained, elevated Pdet during filling; (4) elevated DLPP (>40 cm

H_2O); and (5) elevated voiding pressures in the setting of poor flow.

Frequency of Testing

The CDC National Spina Bifida Patient Registry published a urology protocol in 2016 that discusses, at least from a research perspective, how often centers (21 total centers across the United States as of 2018) will perform various testing in spina bifida patients (Routh et al., 2016). These patients tend to be the most frequent patients who undergo regular urodynamics. The protocol specifies that a baseline study be obtained at around 3 months, and is repeated at 1, 2, and 3 years of age. If there is vesicoureteral reflux or a “hostile” bladder, urodynamics will be repeated yearly thereafter up to 5 years of age. The pediatric urology community hopes to learn more from this registry protocol about the ideal interval of testing in general (e.g., imaging, labs, renal and bladder ultrasonography).

With regard to clinical practice, there are primarily two schools of thought: (1) annual testing with or without imaging (video urodynamics) and (2) limited testing in response to changes in clinical status (e.g., new urinary tract infections, new-onset or worsening incontinence, new-onset or worsening hydronephrosis). One argument against the limited testing approach is that hydronephrosis is not a particularly sensitive indicator of changing bladder dynamics. Kaufman et al. demonstrated this in 1996, when they published on 214 spina bifida patients who had undergone regular renal and bladder ultrasonography and urodynamics (Kaufman et al., 1996). Upper tract hydronephrosis responded well to changing therapy (increased frequency of clean intermittent catheterization or overnight catheter drainage), but on follow-up urodynamics, patients with poor compliance did not show appreciable improvements in urodynamic parameters of the lower urinary tract. In this study, 34 children (16%) went on to have surgery. The counterargument to yearly surveillance urodynamics is the increased cost and the number of studies needed to detect a meaningful change in bladder pressure or compliance to require intervention. Most agree, at a minimum, that regular follow-up of patients with neurogenic bladder is important to ensure safe upper tracts, adequate emptying of the bladder, and minimization of risk for urinary tract infection. Should any of these clinical parameters change, then further investigation is warranted.

Key Points

- Urodynamics is the gold standard for evaluation and diagnosis of lower urinary tract dysfunction.
- Universal strategies of antibiotic prophylaxis or urine cultures before urodynamics do not appear to be effective at preventing postprocedure urinary tract infection, which occurs 1.4% of the time.
- Special considerations in pediatric urodynamics include use of sedation for catheter placement and/or the procedure itself and bladder fill rate, accounting for the varied expected bladder capacities across a wide range of patient ages and sizes.
- Concepts of bladder capacity, Pves, Pabd, Pdet, compliance, timing of loss of compliance, DLPP, ALPP, Pdet at maximum flow, detrusor-sphincter dyssynergia, and PVR are all key components that must be meticulously understood by providers interpreting pediatric urodynamics.
- DLPP and ALPP are different concepts, with DLPP more emphasized in pediatric urodynamic testing as it relates to preservation of or risk to the upper urinary tract.

Evaluation Strategies for Specific Clinical Entities

Lower urinary tract dysfunction encompasses a wide range of diagnoses, pathologies, and possible underlying etiologies. The more common scenarios the pediatric urologist might encounter in practice are discussed here to provide context for clinical evaluation and diagnostic workup.

Non-Neurogenic Lower Urinary Tract Dysfunction

This group includes patients with bowel and bladder dysfunction (overactive and underactive bladder, voiding postponement), nonmonosymptomatic enuresis (daytime urinary symptoms plus nocturnal enuresis), and primary monosymptomatic nocturnal enuresis. These patients may complain of urgency and frequency, and they may have incontinence during the day and/or at night. There is an increased risk for urinary tract infections in these patients, which sometimes confounds the diagnosis. These functional lower urinary tract symptoms may be predominantly storage- or emptying-related.

The large majority of these patients can be diagnosed with a thorough clinical history, physical examination, selective use of noninvasive testing (see later), institution of behavioral and diet changes, and use of appropriate medications targeting the lower urinary tract (e.g., anticholinergics, alpha blockers). Routine use of formal urodynamics in this patient population was found to be low yield, and study information rarely alters choice of therapy in most cases (Parekh et al., 2001). This was confirmed in a prospective manner by the European Bladder Dysfunction Study in 2008 in patients with urgency and voiding dysfunction, who showed no correlation between urodynamics and treatment outcomes (Bael et al., 2008).

There is, however, a small subset of patients who fail conservative, second-line, and even third-line therapies for non-neurogenic voiding dysfunction. Patients with persistent symptoms are at increased likelihood of positive, actionable findings on urodynamics (Kaufman et al., 2006).

Spinal Dysraphism

Many of these patients are referred to urology with a known diagnosis (myelomeningocele accounts for 90% of open spinal dysraphism). Most require ongoing diagnostic study, evaluation, and aggressive treatment to preserve the upper tracts and monitor lower urinary tract dynamics, which change with time (Satar et al., 1995; Kaefer et al., 1999). The more challenging patients are those with possible underlying occult spinal dysraphism (e.g., tethered cord) or other etiologies causing neurogenic bladder. These patients may have only subtle outward evidence of neurologic compromise, and some may only present with changes in the urinary tract. Regardless of the underlying cause, the goal of the urologist is to document and help achieve normal bladder volume, low storage pressures (normal bladder compliance), complete emptying, and adequate protection of the upper urinary tract. Urodynamics is especially useful to this end. Repeat study should be performed before surgical interventions, ensuring that the correct procedure(s) have been planned for the patient.

Sacral Agenesis

Sacral agenesis involves partial or complete absence of the sacrum and is associated with disordered nerve formation at those levels. Patient symptoms vary considerably, as there is no strict correspondence between radiographic and clinical presentation. Nearly one-third of patients remain undiagnosed until later in childhood and present with incontinence, inability to toilet train, or urinary tract infection prompting urologic workup. Examination findings include flattened buttocks, lacking upper portion of the gluteal cleft, and missing sacrum/coccyx on palpation. Diagnosis can be confirmed with a plain radiograph, and this diagnosis may be discovered incidentally in some cases. Urodynamic studies are indicated if voiding dysfunction is present and may show either areflexic bladder with little external sphincter function or DO and concomitant detrusor-sphincter dyssynergia (Guzman et al., 1983).

Anorectal Malformations

Anorectal malformations are commonly associated with abnormalities of the spinal cord like tethering. A tethered spinal cord involves fixation of the conus medularis within the spinal canal, often to L1 or L2. Normally, this structure is freely floating, and termination of the spinal cord rises as children experience axial growth. When fixed, however, the spinal cord is increasingly under traction, and patients may experience gait changes, disordered sensorium of the lower extremities and perineum, and lower urinary tract dysfunction. Although urinary tract symptoms may not be immediately present at birth when the diagnosis of anorectal malformation is made, most recommend a baseline urodynamics study (even in the absence of spinal cord abnormality), particularly after surgical repair (Taskinen et al., 2002; Mosiello et al., 2003). Patients should be monitored and counseled as to changes in urologic function, which should prompt repeat study.

Posterior Urethral Valves

Posterior urethral valves remain the most common underlying cause of lower urinary tract obstruction in boys, and about 15% will progress to have “valve bladder syndrome” (Podestá et al., 2000). In these patients, bladder dysfunction is associated with progressive hydronephrosis and chronic kidney disease (Mitchell, 1982). A large proportion of patients will experience DO and loss of compliance with progression to myogenic failure (Ghanem et al., 2004; Glassberg, 2001; Peters et al., 1990). Patients can also have a component of polyuria secondary to nephrogenic diabetes insipidus that can hamper efforts to maximize bladder emptying. As with other pathologic conditions affecting lower urinary tract function, bladder dynamics in posterior urethral valve patients can change with time. Regular follow-up with urology is important, as changes in clinical status should prompt escalation of care and additional study.

Pelvic Tumors Requiring Extirpation

Resection of pelvic tumors, like sacrococcygeal teratoma, a rare germ cell tumor in neonates, is well-recognized to cause lower urinary tract dysfunction in as many as 50% of patients postoperatively (Malone et al. 1990; Gabra et al., 2006). The proposed mechanism of injury is disruption of the sacral plexus of nerves to the bladder. Urinary symptoms may not be obvious in the newborn period, but ongoing monitoring and high-index of suspicion should be used in these patients to avoid underdiagnosis of bladder dysfunction. Urodynamic testing will often reveal a wide range of pathologies, including DO, detrusor-sphincter dyssynergia, and bladder areflexia (Boemers et al., 1994; Ozkan et al., 2006).

Cerebral Palsy

Voiding dysfunction commonly affects patients with cerebral palsy (up to one-third). The underlying neurologic injury is typically an upper motor neuron lesion, and many these patients present with irritative voiding symptoms (Decter et al., 1987). A standard stepwise approach to workup is warranted in these patients, beginning with a thorough clinical evaluation and implementation of conservative therapies. In select patients who respond poorly to therapy escalation and who desire an improved outcome, urodynamics may be warranted. Common findings at urodynamics include increased bladder capacity, incontinence, detrusor underactivity and overactivity, and rarely sphincter dyssynergia (Mayo, 1992; Richardson and Palmer, 2009).

Spinal Cord Injury

Spinal cord injury causing voiding dysfunction has both an acute and chronic/stabilizing phase. Initially in the acute period after a spinal cord injury, spinal shock results in urinary retention. Implementation of a bladder drainage program should be instituted. A large study of 42 pediatric spinal cord injury patients with at least 1 year of follow-up demonstrated a wide variety of voiding dysfunction phenotypes (Generao et al., 2004). Unsurprisingly, higher lesions (cervical and thoracic) were more associated with detrusor-sphincter dyssynergia than lower lesions (lumbar). In the United Kingdom, guidelines for spinal cord injury workup and management provide that video urodynamics be performed at baseline around 3 to 6 months after the injury, and surveillance urodynamics be performed at follow-up visits for new signs of deterioration, changing management objectives, or follow-up of previously “unsafe” findings (e.g., loss of bladder compliance) (Abrams et al., 2008).

Transverse Myelitis and Other Central Nervous System Disorders

Transverse myelitis is an inflammatory condition of the spinal cord and causes a presentation similar to that of spinal cord injury. There is an acute spinal shock phase followed by a chronic phase. One large series by Tanaka and Kurzrock found that at 7.1 years after onset of disease, 40% to 50% of patients have functional motor recovery, but 86% still had voiding dysfunction, and 77% had complaints of bowel dysfunction (Tanaka et al., 2006). Motor recovery and lower extremity spasticity did not correlate with bladder function. Common findings at initial urodynamics were DO (59%), loss of compliance (47%), sphincter dyssynergia (41%), and detrusor leak point pressure (DLPP) above 40 cm H_2O (12%). The authors recommend early evaluation with ultrasonography and urodynamics with institution of clean intermittent catheterization to preserve the upper tracts.

Acknowledgments

We would like to thank Drs. Paul Austin and Gino Vricella for their contributions to the previous edition of this chapter.

Management Strategies for Vesicoureteral Reflux

Antoine E. Khoury MD, FRCSC, FAAP, Elias Wehbi MD, FRCSC

Vesicoureteral reflux (VUR) is the retrograde flow of urine from the bladder to the upper urinary tract. Despite VUR being a relatively common condition, there are many clinical challenges that arise. VUR has been associated with upper tract damage, such as the presence of scarring, and can be associated with congenital renal dysplasia. Historically, it has been treated in a relatively dichotomous fashion, however, more recently, there is emerging literature on the need to view VUR as a spectrum of disease and to treat those with the condition more on the basis of risk stratification. Despite multiple large randomized studies, which have attempted to address several key issues with the medical management of VUR, there remain many unresolved questions regarding the etiology, diagnosis, and medical management of VUR.

This chapter sheds light on these many issues, which have arisen and continue to evolve and offer a perspective to the modern medical management of VUR in children.

Historical Perspective

VUR has a unique distinction of having evolved from an anatomic curiosity around the first century AD into one of the most contentious and complex areas of urology today. Galen and da Vinci made the first references to VUR by Western medicine when they alluded to the ureterovesical junction (UVJ) as a mediator of unidirectional flow of urine from the kidneys to the bladder. Although VUR was first demonstrated to be a normal finding in dogs and rabbits by Semblinow in 1907, it was a gynecologic misadventure that revealed to Pozzi in 1893 that VUR in human adults may not be a normal state (A Treatise on Gynaecology: v. 3, 1893). In 1907, Sampson suggested that the oblique course of the ureter through the bladder wall created a locking mechanism at the UVJ and also was the first to imply that VUR might lead to renal infection. Although Young was able to uniformly demonstrate VUR in all people in cadaveric studies performed in the late 19th century, it was Gruber who was able to dissect the UVJ more clearly and realized the incidence of VUR varied with the length of the ureter in the bladder and the formation of the trigone (Gruber, 1929).

Pivotal discoveries occurred when Hutch reported on a relationship between VUR and chronic pyelonephritis in paraplegic patients, and Hodson observed that urinary tract infection (UTI) and renal scarring carried a high likelihood of VUR in children (Hutch, 1952, 2002; Hodson, 1959).

Two seminal bodies of work defined the modern era of VUR. First, Ransley and Risdon defined the pathophysiology of reflux nephropathy by demonstrating the relationship between infection, reflux, and pyelonephritic scarring (Ransley and Risdon, 1979). Second, these observations complemented the clinical studies of Smellie et al., who galvanized the related concepts inherent in clinical UTI, bacterial pyelonephritis, renal scarring, and VUR (Smellie et al., 1991). In 1985, a consensus system for the grading of reflux was published by Lebowitz et al. on the basis of the International Reflux Study Group's deliberations (Lebowitz, et al., 1985).

The virtues of medical therapy to avert infections and surgical therapy to correct reflux have been debated for more than 25 years. This debate has further evolved with the introduction of the biodegradable dextranomer and hyaluronic acid for use in endoscopic correction of reflux, and re-examination of the universal need for continuous antibiotic prophylaxis (CAP) and the importance of bowel and bladder dysfunction (BBD). Although the fundamental biologic importance of reflux disease is not in question, many facets of how reflux diagnosis and management are approached may take new shape in the coming decade.

Demographics

Prevalence

Assessing the prevalence rate of a condition that is known to at times be transient is difficult. The tendency for VUR to resolve spontaneously on one hand or persist beyond its natural resolution rate because of abnormal bladder dynamics or associated conditions makes it difficult to confidently generalize the true prevalence of reflux for a given population. In 1967, Köllermann and Ludwig attempted to identify the prevalence of VUR in children admitted to hospital for nonurologic conditions, and after preforming voiding cystourethrography (VCUG) on 103 children, they detected an overall incidence of 30% (29/103) with a higher relative rate in infants 0 to 12 months of age (*n* = 19) compared with children 1 to 5 years of age (*n* = 10) (Köllermann and Ludwig, 1967).

Another study attempted to answer this question with voiding ultrasonography in newborns, examining 2000 children. After a complete workup of children deemed to be at higher risk for VUR based on sonographic findings at time of birth, a rate of VUR of 0.8% was detected (Hiraoka et al., 1999). There is also historical literature evaluating children undergoing cystography for various indications beyond UTIs and estimated its prevalence. An important meta-analysis by Sargent revealed the prevalence of reflux was **estimated to be approximately 30% in children with UTIs and 17% in those who had imaging cystography for other reasons, such as hydronephrosis** (Sargent, 2000). In another study, 157 adults with incidental hypertension without any evidence of renal abnormality were investigated using suprapubic injection of Technetium-99m (^{99m}Tc) into a full bladder. The overall prevalence of VUR was estimated to be 19%, with high-grade reflux in more than one-half of the refluxing group (Barai et al., 2004).

In asymptomatic infants followed for antenatal hydronephrosis, the prevalence of reflux ranges from 15% in those with absent or mild hydronephrosis on postnatal ultrasonography (Phan et al., 2003) to 38% in a group with various postnatal upper tract sonographic anomalies, including hydronephrosis, renal cysts, or renal agenesis (Zerin and Leiser, 1998).

In more recent studies, the prevalence over time has been known to fluctuate and be closely related to the sex of the child and is discussed in the subsequent section.

Sex

There has long been an accepted difference in the rates of VUR in males and females, with conflicting results in the literature. Multiple studies have shown higher rates of VUR in males over females earlier in life, with prevalence rates shifting with age. These differences may suggest a gender dichotomy in the function of the lower urinary tract, bladder outlet, and urethra. A large study from Chand et al. showed that females were almost twice as likely to have reflux as males (Chand et al., 2003), and another more **recent study showed that the male:female prevalence of VUR can be as high as 3:1 at 0 to 6 months of age but shifts to approximately 1:1 by 21 to 24 months of age** (Capozza et al., 2017).

A confounding factor in understanding true sex differences in reflux between males and females is the sex-driven predisposition to UTI. The greater incidence of UTI results in more frequent evaluation and therefore detection of VUR. For example, several studies have shown that there is a 10- to 12-fold increased risk for UTI in uncircumcised infant males (1% compared with 0.12%), (Wiswell, 1992; Morris and Wiswell, 2012; Jagannath et al., 2012), explaining the higher rates of VUR detection in this group. In a related finding, only 10% of patients entered into the International Reflux Study in Children from the United States were boys compared with 24% entered from Europe. The circumcision rate in the latter group was only 5% compared with 62% in the US group ($P < .001$). In some studies, circumcision was more effective in decreasing the risk for breakthrough UTI (BUTI) than antibiotic prophylaxis or antireflux surgery (Kwak et al., 2004; Alsaywid et al., 2010). Similarly, females have a higher propensity for UTI after the first year of life and in childhood relative to males, resulting in higher rates of VUR detected in girls (Zorc et al., 2005).

Reflux in the Fetus

Prenatally detected hydronephrosis is common, estimated to occur between 1% to 5% of pregnancies (Braga et al., 2017). Traditionally, the recommendation was to screen these infants for VUR (Nguyen et al., 2010; St Aubin et al., 2013). **However current indications for obtaining a VCUG in the newborn period are limited to those with findings on renal bladder ultrasonography (RBUS)**

indicative of higher risk for significant VUR, such as higher grades of hydronephrosis (particularly bilateral hydronephrosis), renal cortical abnormalities, ureteral dilation, suspicion of anatomic anomalies such as ureteroceles or duplication of the collecting system, and bladder abnormalities.

In older studies in which infants were screened with VCUG, **VUR was found in 10% to 40%** (Lee et al., 2008; Peters and Rushton, 2010; Yeung et al., 2017), and up to 19% having bilateral VUR (Yeung et al., 2017; Zerin et al., 1993). There was a significantly higher incidence of bilateral dilating VUR, up to 80%, in children who initially presented with prenatal hydronephrosis (Evans et al., 2015).

VUR in these infants is likely of low clinical significance because the incidence of pyelonephritis is rather low, as demonstrated in the study by Zee et al., who evaluated a cohort of 213 infants with prenatal hydronephrosis, of which 133 had VCUG as part of their workup. In this group, only 19% (25/133) had VUR, and only two went on to develop a UTI (Zee et al., 2016).

Another important study by Estrada et al. showed a slightly different incidence of febrile UTIs in patients with hydronephrosis who were either initially screened with VCUG or followed with ultrasonography alone (Estrada et al., 2009b). In this study, the incidence of VUR was 28%. The rate of UTI in screened patients with and without VUR was 1.6% and 1.3%, respectively, although those with VUR were on prophylactic antibiotics. One interesting finding was that there was a significantly higher rate of UTI (4.4%) in a group of patients who did not undergo an initial VCUG but went on to have a febrile UTI. In this cohort, when a VCUG was performed, 75% (12/16) had VUR.

These studies further emphasize the importance of individualizing care, and extreme approaches for either obtaining or limiting routine VCUG in the evaluation of a child with hydronephrosis should be tempered.

Age

It is well accepted that reflux is significantly more common in younger children and may resolve spontaneously over time (Garcia-Roig et al., 2017). Resolution rates are multifactorial, and the prevalence of VUR for a given age is difficult to assess, however, one large study by Chand et al. provides a review of a large cohort and found that in children who present with UTIs, the incidence of VUR for patients ages less than 2, 2 to 6, 7 to 11, and 12 to 21 years was 38.6%, 26.9%, 19.7%, and 7.6%, respectively (Table 29.1).

TABLE 29.1

Incidence of Reflux in Patients With Urinary Tract Infections

AGE (YEARS)	INCIDENCE (%)
<2	38.6
2–6	26.6
7–11	19.7
12–21	7.6

From Chand DH, Rhoades T, Poe SA, et al., Incidence and severity of vesicoureteral reflux in children related to age, gender, race and diagnosis. *J Urol*. 2003;170(4):1548–1550.

Race

Significant racial differences exist, notably in the prevalence and impact of VUR. In older studies, **up to a 10-fold reduction in VUR in female children of African descent was observed** (Skoog and Belman, 1991)**. More recently, this difference appears to decrease to threefold** (Chand et al., 2003), possibly because of narrowing socioeconomic differences, an increase in prevalence of interracial families, and improved access to care. What was interesting in this study was the absence of grade IV and V VUR in the cohort of African-American children who were younger than 6 years, underscoring the significant racial differences in rates of VUR (Chand et al., 2003).

In the Randomized Intervention for Children with Vesicoureteral Reflux (RIVUR) study, 80% of patients enrolled were Caucasian (RIVUR Trial Investigators et al., 2014). In a series of non-Caucasian children with a 4:1 male-to-female ratio, 58% of whom were younger than 1 year of age presenting with UTI (72%), voiding difficulties (10%), or other malformations (14%), reflux was present in only 10% (West and Venugopal, 1993). Even in follow-up for antenatal hydronephrosis, reflux was found in 17.6% of 51 non-black versus 0% of 58 black infants (Horowitz et al., 1999). The stark contrast in rates of reflux disappear over time and likely with maturation of the antireflux mechanism in Caucasian children as the race-associated frequency of reflux becomes equal after 10 years of age (Melhem and Harpen, 1997).

Key Points: Demographics

- The younger the child with UTI, the greater is the likelihood of discovering reflux.
- Males may tend to have higher rates of UTI earlier in life, but this contrast is overshadowed by diagnosis of VUR in females who present with UTI.
- VUR is relatively rare in children of African descent.

Inheritance and Genetics

Sibling Reflux

There has been a clearly established body of literature evaluating the connection between VUR in siblings. The prevalence of VUR in siblings of affected children, who mostly present with UTIs, is roughly **30% but has been as high as 50%** in some studies (Nelson et al., 2016; Giannotti et al., 2011; Ataei et al., 2004; Cordell et al., 2010; Menezes and Puri, 2009; Puri et al., 2011; Hollowell and Greenfield, 2002).

This increased prevalence, however, may be more relevant for younger siblings. In one study by Menezes et al., VUR was present in almost 88% of siblings who were screened and who were younger than 3 years of age. In this study, a group of symptomatic siblings who had UTIs also had a high rate of high-grade VUR and a higher incidence of renal scarring (36%) (Menezes and Puri, 2009). The authors therefore concluded that siblings who are younger than 3 years of age of patients who present with VUR grade III to IV should be screened. One of the limitations of this study is that only index patients with VUR grade III to IV were included, and so recommendations can only be made for siblings younger than 3 years of age, whereas no recommendations can be made for siblings of patients with VUR grades I and II, who form the majority of patients with VUR (RIVUR Trial Investigators et al., 2014).

Another study found that the incidence of VUR in older siblings may be as low as 7% in keeping with known spontaneous resolution rates over time (Connolly et al., 1996). This differed from the results of a report by Ataei et al., which showed similar rates of VUR in siblings above and below a cutoff age of 6 years (Ataei et al., 2004).

Identical twins may be a unique subset of patients as these siblings may have a higher rate of sibling VUR. One study by Kaefer et al. showed a 100% concordance rate in identical twins (Kaefer et al., 2000).

In a study by Giannotti et al. of 251 families with at least two siblings with VUR, the incidence of VUR in twins was evaluated. There were 12 families with affected twins having an index sibling who presented with reflux and a twin diagnosed either through screening or having presented with infection herself. Only two siblings of index patients had infection (2/12, 17%), whereas the remaining 10 (83%) were diagnosed after screening (Giannotti et al., 2011).

Although the majority of twin siblings were female with higher grades of VUR, none of them showed evidence of renal scarring on diagnostic workup, compared with 3/12 (25%) of their twins, who were the index patients.

The high rate of VUR in twin sibling studies **supports the notion of some hereditary impact on VUR,** and although a heightened prevalence of reflux exists in siblings of refluxing index patients, given the known tendency for reflux to resolve spontaneously, one would also expect a lower incidence of VUR in older siblings (Connolly et al., 1996).

When considering the impact of VUR on siblings, the impact of screening is important to consider, especially in patients who may be asymptomatic. This needs to be balanced with the presence of clinically meaningful VUR, where diagnosis and some form of treatment may be beneficial. In one retrospective study of 123 screened siblings, 44 (36%) demonstrated VUR on VCUG (Houle et al., 2004). Of these patients, 37 underwent renal imaging. Ultrasonography was abnormal in 30% and renal scintigraphy, when used, was abnormal in 28%. However, in siblings older than 2 years of age, renal scintigraphic abnormalities were twice as common as in the entire group of siblings. The authors concluded that renal damage is therefore progressive in the older siblings and proposed earlier screening of siblings of refluxing index patients. However, this study fails to address the fact that renal damage may have occurred very early, and over time (beyond 2 years of age), renal growth may have exaggerated the appearance of such scintigraphic abnormalities. Finally, the reporting of scintigraphic results by many sibling reflux studies is confounded by failing to differentiate between congenital parenchymal changes often associated with higher grades of reflux and true scarring secondary to infection and inflammation. In the absence of such data and faced with the invasive nature of a VCUG, one is left with the following question: Is asymptomatic reflux in a sibling of clinical concern? If the propensity for UTI, with or without VUR, could be reliably determined to be genetically regulated, it would strengthen the case for screening siblings for reflux. Because risk for infection cannot be readily determined in either an index patient or his or her sibling, the likelihood of developing a UTI as a justification for screening siblings for reflux should be cautioned. **Because it is the likelihood of renal damage, higher in certain scenarios, that can be associated with reflux that is the issue, rather than reflux itself, siblings may be better served by noninvasively screening for cortical abnormalities first, and screening for reflux if history of compounding factors such as UTI or BBD are present.** The intensity of renal imaging, using ultrasonography for general screening or a nuclear scan for highest accuracy, could then be tempered by clinical factors, including family history, patient and family compliance with follow-up, blood pressure, a history of UTI and fever, and voiding dysfunction. The absence of renal imaging abnormalities would allow the clinician to conclude with some confidence that reflux, if present, has not resulted in significant renal damage. This approach to screening siblings, particularly the group of index patients who present with high-grade VUR, is especially appealing as further **workup can be individualized based on the perceived risk of the sibling** (Springer and Subramaniam, 2014).

Should screening depend on sibling age? Because the risk for new renal scarring after pyelonephritis is lower in older children (Menezes and Puri, 2009), older siblings would likely suffer fewer consequences from reflux-induced pyelonephritis and therefore stand to benefit less from confirming a diagnosis of reflux and instituting antibiotic prophylaxis over an infant or younger sibling.

Imaging the kidneys to assess the impact of VUR, if any, provides a rational initial approach to sibling screening. If consideration of age and renal integrity is combined, a possible graded approach to screening can be developed for older siblings with or without renal structural abnormalities. The urologic and voiding history must also play a deciding role in whether a sibling is ultimately screened by a VCUG for VUR. Thus, in older siblings with normal kidneys on ultrasound and without BBD, little would be gained from detecting reflux that could not be addressed by responding to a febrile UTI in the usual fashion as for the general pediatric population. In the younger siblings, especially those with BBD or who are not toilet trained, a normal ultrasound scan serves as part of the bases for clinical judgment regarding the likelihood for infection rather than an immediate need to diagnose reflux. In any sibling, if reflux is diagnosed, the indications for reflux correction remain the same as for the general refluxing pediatric population.

The American Urological Association (AUA) 2010 VUR guidelines recommend screening siblings of children with VUR with a VCUG if there is evidence of cortical abnormalities on ultrasound or a history of UTI. This is especially important in the presence of grade 3 to 4 hydronephrosis on ultrasonography (Skoog et al., 2010). It is also reasonable to take an observational approach to screening, especially for those with grade 1 to 2 hydronephrosis (Skoog et al., 2010).

Genes Involved

In addition to sibling reflux, a prospective screen of progeny of patients with reflux revealed a 66% rate of reflux in the offspring (Noe et al., 1992). Familial VUR most closely conforms to an autosomal-dominant inheritance pattern, but because of variable penetrance and expressivity, large multigenerational pedigrees traceable to linkage analyses have been difficult to ascertain (Sanna-Cherchi et al., 2005).

The substantially higher rate of reflux in siblings and progeny of index patients compared with the general population defines these patients as susceptible to reflux and potentially associated renal morbidity. Previous segregation and linkage analyses have implicated a number of loci in the pathogenesis of VUR, though no specific gene product or functional role for these loci in reflux has yet been identified (Darlow et al., 2017).

Moreover, formation of multiple ureteric buds may also lead to short duplex ureters, duplex kidneys, and ectopic and dysplastic kidneys (Nino et al., 2016; Batourina et al., 2005; Grieshammer et al., 2004; Basson et al., 2005; Hains et al., 2010).

This led to the theory that mutations of genes involved in early ureteric bud formation and positioning increases the risk for developing urinary obstruction, VUR, and possibly hydronephrosis during fetal life and after birth in both humans and mice (Hains et al., 2010; Wang et al., 2011; Uetani and Bouchard, 2009).

Several genes have been observed to regulate these developmental processes and, by extension, are believed to serve as potential regulators of UVJ integrity, though their specific connection to VUR is clinically unproved. Indeed, genetic misregulation of ureteric budding is believed to underlie many congenital anomalies of the kidney and urinary tract (CAKUT) (Miyazaki and Ichikawa, 2003).

The subsequent section will discuss current candidate genes or loci that have been implicated, however to date, **despite family-based association analyses of large parent-affected-child trios and case/control association analyses, compared with a large control population, there are no compelling associations between single gene or specific loci linked with nonsyndromic VUR** (Darlow et al., 2017)**.**

Pax2: Paired box gene 2 *(PAX2)* is a transcription factor regulating kidney, central nervous system, and ocular development in mice. It is necessary for ureteric budding in mice (Keller et al., 1994; Lee et al., 2017). *PAX2* is located on human chromosome 10q24, and mutations have been reported in human syndromes involving colobomas and renal anomalies, including hypoplasia, dysplasia, glomerulonephritis, and VUR (Sanyanusin et al., 1995; Lee et al., 2017). However, *PAX2* has not been shown to be a major determinant of primary VUR (Lee et al., 2017; Darlow et al., 2017; Choi et al., 1998; Cunliffe et al., 1998).

Gdnf/RET: Glial-derived neurotrophic factor (Gdnf) and its receptor RET show strong involvement in UVJ formation in mice (Yu et al., 2004; Lee et al., 2017). Overexpression of *RET* in mice leads to abnormal placement of the ureteric bud and is associated with a high incidence, 30% in some studies, of VUR at birth compared with 4% in wild-type mice. Nevertheless, the Gdnf-Ret signaling complex has been found to not mediate VUR in humans (Nino et al., 2016; Shefelbine et al., 1998; Lee et al., 2017). One reason for the conflicting studies in the literature on reflux genetics is that clusters of specific populations with their own inherent genetic backgrounds occasionally amplify a putative gene association for VUR that does not apply to all populations. This is partly why *RET* can show a very high-frequency *RET* polymorphism in patients with primary VUR from one ethnogeographic region but not in a similar cohort of patients with primary VUR in another (Darlow et al., 2009; Nino et al., 2016; Lee et al., 2017).

Uroplakin III: Another fascinating animal model of VUR is observed after deletion of the uroplakin III gene (Hu et al., 2000). However, no structural uroplakin III gene alterations have been noted in human cohorts with VUR (Giltay et al., 2004; Jiang et al., 2004). One explanation for this finding may be that major uroplakin mutations are developmentally lethal in humans.

Osr1: Odd-skipped related 1 *(Osr1)* is a transcriptional repressor that plays critical roles in maintaining the mesenchymal stem cell population within the developing kidney (Fillion et al., 2017). A study in newborn pups with a heterozygous loss-of-function mutation in *Osr1* exhibited a 21% incidence of VUR and had hydronephrosis and urinary tract duplications. Osr1 expression is important in the ureteral mesenchyme and within the developing bladder. Sequencing in 186 affected children revealed variable results, however it may be a candidate gene implicated in the pathogenesis of VUR and CAKUT, although more definitive studies are warranted (Fillion et al., 2017).

10q26 Region: In a large genome-wide linkage and association study, the 10q26 region was a major genetic contributor to primary nonsyndromic VUR. A family-based association analysis, which included 1098 parent-affected-child trios was evaluated. The study also included a case-control association analysis of 1147 affected cases and 3789 matched controls. The analysis did not reveal any significant associations per se, but subsequent parametric linkage analysis of 460 families with more than 1000 individuals identified a single region on 10q26 that showed strong linkage (HLOD = 4.90; ZLRLOD = 4.39) to VUR (Darlow et al., 2017). This region contains more than 65 genes that may serve as candidate genes for further study.

Notwithstanding an observed pattern of autosomal dominant inheritance in some families, the failure to identify any strong genetic mechanism in primary VUR in humans, despite the presence of convincing animal and human genetic models of reflux, argues for a more complex polygenetic mechanism of disease. Indeed, in the large whole-genome linkage and association scans for primary nonsyndromic reflux done to date, no clear overlap involving previously reported genes was found (Cordell et al., 2010; Darlow et al., 2017). Although several areas of the genetic code have been explored, there is still no dominant gene or major gene locus specifically linked to nonsyndromic VUR in any of the populations tested.

See Fig. 29.1 for list of common human genes implicated in CAKUT, including VUR.

Gene	Kidney developmental stage	Location	Signals	Gene product	Disease	Inheritance type	#Gene OMIM	Reference number
Ureteric budding								
RET	Ureteric budding	10p13	GDNF signaling	RTK	Bilateral renal hypodysplasia/agenesis VUR, ureteral obstruction, megaureter, duplex kidney, renal abnormalities, as well as Hirschsprung disease	AR	191830	23,82
PAX2	Ureteric budding	10q24.31	(–)	PAX (paired box domain)	Papillorenal syndrome that comprises renal defects (oligomeganephronia, hypodysplasia, VUR, and cysts) and ocular defects affecting the optic nerve and/or the retina	AD	120330	39,83
EYA1	Ureteric budding	8q13.3	RTK signaling pathway	Eyes absent homolog 1	BO syndrome	AD	602588	26,27
SALL1	Ureteric budding	16q12.1	(–)	Sal-like protein 1 (also known as spalt-like transcription factor 1)	Townes-Brocks syndrome, as well as BOR syndrome	AD	107480	28,29
SIX1	Ureteric budding	14q23.1	(–)	SIX homeobox 1, 2, and 5	BOR syndrome, BO syndrome	AD	608389	30
SIX2	Ureteric budding	2p21	WNT-pathway	SIX homeobox 2	Renal hypodysplasia	NA	604994	31
BMP4	Ureteric budding	17q22.2	BMP-BMPR signaling system	Bone morphogenetic protein 4	Syndromic microphthalmia, orofacial cleft	AD	112262	31
GATA3	Ureteric budding	10p14	(–)	(–)	Hypoparathyroidism, sensorineural deafness, renal dysplasia	AD	146255	84
Development of the metanephric kidney								
ROBO2	Development of the metanephric kidney	3p12.3	SLIT2-ROBO2 signaling pathway	Receptor for the Slit2 ligand	VUR	NA	610878	41
SLIT2	Development of the metanephric kidney	4p15.31	SLIT2-ROBO2 signaling pathway	Slit protein	Cystic dysplastic kidneys, unilateral renal agenesis, and duplicated collecting system	NA	603746	41,44
SRGAP1	Development of the metanephric kidney	12q14.2	SLIT2-ROBO2 signaling pathway	SRGAP1(small GTPase activating protein)	Cystic dysplastic kidneys, unilateral renal agenesis, duplicated collecting system	NA	606523	44
MET								
WNT4	MET	1p36.12	WNT pathway	Protein Wnt-4	Müllerian aplasia, hyperandrogenism	AD	158330	47
FGF20	MET	8p22	(–)	Fibroblast growth factor 20	Renal hypodysplasia/aplasia	AR	605558	50
RAS								
AGT	RAS	1q42.2	RAS pathway	Angiotensinogen	Renal tubular dysgenesis	AR	106150	53
REN	RAS	1q32.1	RAS pathway	Ren	Renal tubular dysgenesis	AR	179820	53
ACE	RAS	17q23.3	RAS pathway	Angiotensin converting enzyme	Renal tubular dysgenesis	AR	106180	53
AGTR1	RAS	3q24	RAS pathway	Angiotensin II receptor type 1	Renal tubular dysgenesis	AR	106165	52
Nephron patterning and elongation								
Uromodulin (UMOD)	Nephron patterning elongation	16p12.3	(–)	Tamm-Horsfall protein (uromodulin)	Medullary cystic kidney disease type 2, familial juvenile hyperuricemic nephropathy, and glomerulocystic kidney disease	NA	191845	54,55
Unknown								
TRAP1	Unknown (possibly antiapoptotic and endoplasmic reticulum-stress signaling in proximal tubules and in thick medullary ascending limbs of Henle's loop.)	16p13.3	(–)	TRAP1 heat shock protein 75 (also known as TNF receptor associated protein1-mitochondrial HSP90 protein)	CAKUT or CAKUT in VACTERL	NA	606219	61
HNF1B	Unknown (possibly wolffian duct from a very early developmental stage of the kidney)	17q12	(–)	HNF1B protein	Renal cysts and diabetes syndrome also referred to as MODY5, renal hypodysplasia, multicystic dysplastic kidney, cystic kidney diease, single kidney, oligomeganephronia	AD	189907	83
PKHD1	(–)	6p12.3-p12.2	(–)	Protein fibrocystin	Autosomal recessive polycystic kidney polycystic kidney, and hepatic disease	AR	606702	59
KAL1	(–)	Xp22.31	FGF signaling, that there is an interaction between anosmin-1 and FGFR1	Anosmin 1	VUR, hypogonadotropic hypogonadism 1 with or without anosmia (Kallmann syndrome)	XL	300836	64,65
HOXA13	(–)	7p15.2	(–)	Homeobox protein	VUR, hand-foot-genital syndrome, Guttmacher syndrome (preaxial deficiency, postaxial polydactyly, and hypospadias)	AD	142959	67
NIPBL	(–)	5p13.2	(–)	Delangin	VUR, cornelia de Lange syndrome	AD	608667	68

FIG. 29.1 Genes, signaling pathways, and defects linked to clinical phenotypes of congenital anomalies of the kidney and urinary tract (CAKUT). (–), Unknown; *AD,* autosomal dominant; *AR,* autosomal recessive; *BO,* branchio-otic; *BOR,* branchio-oto-renal; *FGF,* fibroblast growth factor; *FGFR1,* FGF receptor 1; *HSP,* heat shock protein; *GDNF,* glial cell-line–derived neurotrophic factor; *MET,* mesenchymal-to-epithelial transition; *MODY,* maturity-onset diabetes of the young; *NA,* not applicable; *OMIM,* Online-Mendelian inheritance in man; *RAS,* renin-angiotensin system; *RTK,* receptor tyrosine kinase; *TNF,* tumor necrosis factor; *VACTERL,* combination of at least three of the following congenital anomalies: vertebral defects (V), anorectal malformations (A), cardiac defects (C), tracheoesophageal fistula with or without esophageal atresia (TE), renal malformations (R), and limb defects (L); *VUR,* vesicoureteral reflux; *WNT,* wingless and integration site growth factor. (Data from Lee KH, Gee HY, Shin, JI. Genetics of vesicoureteral reflux and congenital anomalies of the kidney and urinary tract. *Investig Clin Urol.* 2017;58(Suppl 1):S4–S13.)

Key Points: Screening, Inheritance, and Genetics

- The prevalence of reflux is higher in siblings.
- Probably multiple genes are involved.
- It cannot be assumed that all cortical abnormalities in refluxing siblings are acquired.
- Mass screening of siblings is unnecessary, and clinicians should be selective based on sibling risk profile.

Embryology of the Ureterovesical Junction

A full discussion of the embryology of the trigone and ureteric orifice is found elsewhere in this text. In brief, two events proceed simultaneously to govern the ultimate position and integrity of the UVJ. At one point, the embryonic ureter buds from the mesonephric (or Wolffian) duct to form the metanephric duct or early fetal ureter. The Wolffian duct (early vas deferens) and early ureter can be thought of as forming the two upper arms of a *Y* with the distal mesonephric duct as the stem of the *Y*. Although budding is occurring, the distal mesonephric duct is being drawn and incorporated into the region of the urogenital sinus (UGS), which later becomes the bladder. Incorporation continues until the entire stem is absorbed, leaving the two arms of the Y to enter the bladder separately—one as the ureter and the other as the vas and ejaculatory duct in the male prostatic urethra (or the vestigial Gartner duct in the female vagina). Seminal embryologic work by Mackie and Stephens showed that the two arms of the Y also rotate relative to each other once they contact the UGS/bladder wall, resulting in the ureteric orifice being proximal to the ejaculatory duct orifice. If the ureteric bud reaches the UGS too soon (thought to be caused by early budding), overrotation draws it high and lateral in the bladder wall, leading to inadequate incorporation, insufficient intramural length in the bladder wall, and reflux (Mackie et al., 1975). If the ureteric bud reaches the UGS too late (because of late budding), insufficient rotation occurs, resulting in an ectopic ureter that is drawn distally and medially, often obstructing in the bladder neck region or elsewhere. Furthermore, early or late budding is also thought to affect the contact between bud epithelium and the metanephros, leading to renal malformations, dysplasia, hypoplasia, or even agenesis.

To further augment the work by Mackie and Stephens, Batourina showed that the nephric duct might not differentiate into the trigone but undergo apoptosis, a pivotal step for transposition of the ureter (Batourina et al., 2005). This step may be mediated by vitamin A–induced signals from the primitive bladder.

Functional Anatomy of the Antireflux Mechanism

The phenomenon of VUR represents a balance of several factors. Abnormality in any of these factors alone or in combination will allow or cause the retrograde flow of urine from the bladder up the ureter and ultimately to the kidney. These factors include the functional integrity of the ureter, the anatomic composition of the UVJ, and the functional dynamics of the bladder.

First, for purposes of reflux prevention, the ureter represents a dynamic conduit, which propels a bolus of urine antegrade by neuromuscular propagation of peristalsis. In so doing, reflux is actively opposed.

The second component is the anatomic design of the UVJ. At the heart of this unique mechanism lies an intramural portion of ureter that travels within the detrusor muscle as it traverses the bladder wall (Fig. 29.2) (Elbadawi, 1972). At the extravesical bladder hiatus, the three muscle layers of the ureter separate. The outer ureteral muscle merges with the outer detrusor muscle to form Waldeyer's sheath, which contributes to formation of the deep trigone. Interestingly, recent studies have shown that Waldeyer's sheath might not be unique to the UVJ. Rusu et al. used immunohistochemistry to stain proximal ureteric specimens, removed at time of nephrectomy, to show very elegantly that Waldeyer's sheath may not only be present near the UVJ, but that it may be a common anatomic characteristic of the ureter itself (Rusu et al., 2017).

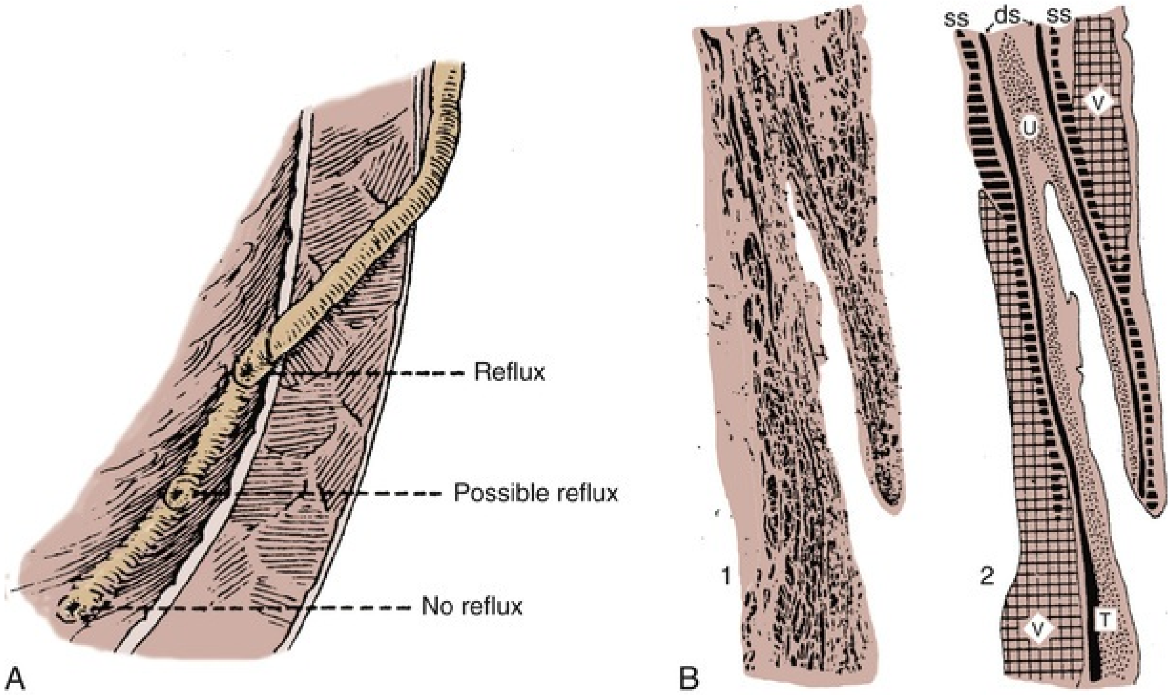

FIG. 29.2 (A) A refluxing ureterovesical junction has the same anatomic features as a nonrefluxing orifice, except for inadequate length of the intravesical submucosal ureter. Some orifices with marginal submucosal tunnels may reflux intermittently. (B) Ureterovesical junction in longitudinal section. *1,* Photomicrograph; *2,* diagrammatic representation. The ureteral muscularis *(U)* is surrounded by superficial *(ss)* and deep *(ds)* periureteral sheaths that extend in the roof of the submucosal segment and continue beyond the orifice into the trigonal muscle *(T)*. The relationship of the superficial sheath to the vesical muscularis *(V)* is clearly seen. Transverse fascicles in the superior lip of the ureteric orifice belong to the superficial and deep sheaths. No true space separates the ureter from the bladder. (A, From Glenn J. *Urologic surgery.* 2nd ed. New York, NY: Harper & Row; 1975; B, from Elbadawi A. Anatomy and function of the urethral sheath. *J Urol*. 1972;107[2]:224.)

The intramural ureter remains passively compressed by the bladder wall during bladder filling, preventing urine from entering the ureter. Adequate intramural length and fixation of the ureter between its extravesical and intravesical points are required to create this antirefluxing compression valve. Paquin's early dissections of the UVJ in children revealed an approximately 5:1 ratio of tunnel length to ureteral diameter in nonrefluxing junctions compared with a 1.4:1 ratio in refluxing UVJs (Paquin, 1959) (Table 29.2).

TABLE 29.2

Mean Ureteral Tunnel Length and Diameter in Normal Children

AGE (YEARS)	INTRAVESICAL URETERAL LENGTH (mm)	SUBMUCOSAL URETERAL LENGTH (mm)	URETERAL DIAMETER AT THE URETEROVESICAL JUNCTION (mm)
1–3	7	3	1.4
3–6	7	3	1.7
6–9	9	4	2.0
9–12	12	6	1.9

From Paquin AJ. Ureterovesical anastomosis: the description and evaluation of a technique. *J Urol*. 1959;82:573–583.

Later on, work by Lyon et al. challenged this theory in part by stating that not only is the length of the intramural tunnel important, but so is the configuration of the ureteric orifice (Lyon et al., 1969). **The importance of ureteric orifice configuration relative to ureteral tunnel length in determining UVJ competence was recently confirmed using computer modeling** (Villanueva et al., 2015). One thing that both these theories lack and what modern surgical techniques do not account for is the intrinsic qualities of the ureter itself in the tunnel and its role in ultimately allowing for ureteric collapse with bladder filling to prevent reflux.

One study that attempts to merge these various concepts uses complex statistical modeling to unify findings from existing studies and accepted dogma. Villanueva et al. modeled ureteral collapse pressure using several of the factors that are known to play a role in tube collapse, beyond the length of the tunnel itself, and found that not only is the pressure required to collapse the ureter inversely related to its diameter (a widely known fact), but that for a ureteral tunnel length greater than 1 cm, pressures required to collapse the ureter did not decrease by any significant amount. If the ureteral thickness or ureteral stiffness increased, an increase in pressure was required to collapse the ureter. This was only significant for ureteral thicknesses not commonly seen in practice (e.g., wall thickness of 2.5 mm in a 6.4-mm–diameter ureter) (Villanueva et al., 2015). Such studies are crucial for the broader understanding of reflux and further challenge long-standing dogma, which, although holds much truth, can oftentimes be too simplistic to explain the complete interconnectedness between the ureter and the bladder in the normal, nonreflux UVJ.

Intravesically, the inner muscle of the ureter merges with the detrusor muscle to contribute to the superficial trigone. Some of these inner ureteral fibers pass medially to contribute to the intraureteric ridge. The cellular and molecular details that characterize normal and refluxing UVJs are still unknown. However, it is likely that in addition to architectural deficiencies of tunnel length, abnormalities in uterovesical smooth muscle and extracellular matrix composition, neural function, configuration of the orifice may contribute to reflux (Oswald et al., 2004; Lyon et al., 1969; Villanueva et al., 2015).

Opening of the UVJ is achieved by active contraction of the longitudinal muscles within the tunnel. This draws the extravesical and intravesical points of the intramural ureter closer together, shortening and widening the tunnel, which allows passage of the urine bolus into the bladder. Indeed, when viewed cystoscopically, a lateral displacement of the ureteric orifice accompanies a jet of urine into the bladder. Although such lateral displacement is functionally normal and necessary to permit urine to pass, permanent lateral displacement by virtue of a short tunnel characterizes the cystoscopic position of the refluxing ureteric orifice. Closure of the UVJ results both from compression of the intramural ureter and a return to its full tunnel length as the ureteral muscle relaxes. Thus active and passive mechanisms dynamically reconfigure the tunnel as needed to allow antegrade passage of urine while preventing retrograde flow. Finally, the existence of local efferent and afferent neuromuscular coordination between the UVJ and the periureteral bladder wall is suggested by neurophysiologic studies that induce elevation or decrease in intraluminal UVJ pressure during bladder filling (Shafik, 1996).

Key Points: Functional Anatomy

- Integrity of the antireflux mechanism depends on balancing the anatomic and functional relationships between the ureter and the bladder.
- Reflux may be of an anatomic or functional origin in the UVJ, bladder, or bladder outlet.

Causes of Vesicoureteral Reflux

The occurrence of VUR represents a balance of several factors. The degree to which each contributes to the pathologic processes largely defines whether reflux is considered primary or secondary. Reflux likely represents an imbalance between dynamic storage and voiding characteristics of the bladder and the architectural competency of the UVJ to resist reflux. If looked at through this lens, one may consider that most reflux indeed may be secondary and in fact may be transient or reversible.

In general, **reflux is considered primary if it is caused by a fundamental deficiency in the function of the UVJ antireflux mechanism while the remaining factors (bladder and ureter) remain normal or relatively noncontributory. Secondary reflux, then, implies reflux caused by overwhelming the antireflux function of the UVJ, either resulting from sustained and repeated increases in intravesical pressures or anatomic anomalies, such as in the case of duplication anomalies and periureteral diverticulae. VUR is also closely tied to the presence of bladder dysfunction, either of a congenital, acquired, or behavioral nature and is often a major contributor to the presence of secondary reflux** (Santos et al., 2017; Shaikh et al., 2016a; Elder and Diaz, 2013). It is also accepted that reflux is often considered secondary if its absence was documented at some point before its detection.

Primary Reflux

As stated earlier, primary reflux represents a congenital defect in the structure and therefore function of the UVJ. Reflux occurs despite an adequately low-pressure urine storage profile in the bladder. The length-to-diameter ratio of the intramural ureteral tunnel is almost always less than that described by Paquin in 1959 (Paquin, 1959).

The interplay as to what ultimately causes reflux is complex and likely involves more than just a simple lack of tunnel length, as what has been historically taught. There are multiple factors that likely play a role beyond inadequate tunnel length and poor or weak detrusor muscle backing. These can include a significantly dilated ureter, intrinsic stiffness of a ureter, and abnormal bladder characteristics, to name a few. The dilated ureter often poses a challenge when a nonrefluxing ureteral reimplant is desired. This has traditionally prompted both long tunnels (>5 cm) or a reduction in ureteral diameter by tapering, plication, or both in an attempt to reconstruct a successful antireflux mechanism. On the other hand, construction of a new tunnel with a full 5:1 length-to-diameter ratio may not be absolutely required to correct reflux (Villanueva et al., 2015).

Secondary Reflux

Secondary VUR occurs in the presence of two distinct settings, either resulting from an **increase in intravesical pressure** or an anatomically **abnormal UVJ.** An increase in intravesical pressure can be broadly considered to arise from outlet obstruction, either mechanical blockage, for example in the presence of posterior urethral valves (PUVs), strictures, or masses, to name a few, or from a functional obstruction, such as in the presence of either neurogenic or non-neurogenic obstruction of the continence mechanisms, as in the presence of bladder sphincter dyssynergia or dysfunctional voiding, respectively. Conditions caused by innate **bladder detrusor pathology** are usually considered to be of either a neurogenic or non-neurogenic origin as well, as in the case of spinal pathology or again, dysfunctional voiding, respectively.

In contrast with anatomic obstruction, neurologic causes of elevated bladder pressures also predispose to VUR. In particular, neurogenic bladder associated with spina bifida is at risk for reflux (Bauer et al., 1982). VUR can be present in up to 30% of patients with neurogenic bladders resulting from spinal dysraphism. This fact must be borne in mind during the evaluation of the child with UTI or incontinence. Special attention to the potential for occult spinal dysraphism, including sacral dimple, hairy patch, gluteal cleft abnormality, diminished rectal tone, or significant and often refractory constipation or encopresis, should prompt consideration for investigation of coexistent spinal cord abnormalities. In those patients who are known to have spinal dysraphism and VUR, a more conservative approach to managing the lower urinary tract is generally advised. This often includes early initiation of clean intermittent catheterization (CIC), consideration for anticholinergic administration, and close follow-up with serial imaging. There should be a low threshold for further diagnostic studies with any evidence of progression, such as worsening hydronephrosis or VUR grade and bladder wall characteristics on VCUG. Urodynamic extremes that predispose to reflux in the absence of abnormal neurologic conditions may also exist. Some studies suggest that a secondary aspect to neonatal reflux is a peculiarity found in male infants. In a study by Yeung et al., 22 of 24 infants with reflux showing urodynamic evidence of overactivity, inadequate, or obstructive voiding patterns were males (Yeung et al., 1998). Normal or immature voiding patterns were observed in all infants in the nonrefluxing control group, of which 16 of 21 were male. In infants, higher voiding pressures are associated with reflux, particularly in boys (Chandra et al., 1996), and may contribute to the male preponderance of reflux in infancy. This would explain the higher gender inequalities within this age range and also the high resolution rates and gender shift, which were previously discussed.

Urodynamic evaluation suggests these elevated infant bladder pressures may be caused by inadequate sphincter relaxation during this stage of development (Chandra et al., 2000). However, detrusor activity in such infants is largely normal during filling, with slightly diminished bladder capacities in some (Podesta et al., 2004), though neurogenic detrusor overactivity during filling has been observed, again predominantly in male infants (Yeung et al., 1998). Considering that the high prevalence for reflux in infants coexists with urodynamic evidence of elevated voiding pressures, these observations suggest that infant voiding patterns may be a part of normal development. Thus, even though the UVJ likely matures with age, the interplay between the UVJ and infant voiding patterns may predispose children, and even more so males, to a form of secondary reflux that resolves as these infants grow older and voiding matures.

In older children, acquired abnormalities in bladder and bowel function, commonly known as *BBD*, have been associated with UTI and reflux.

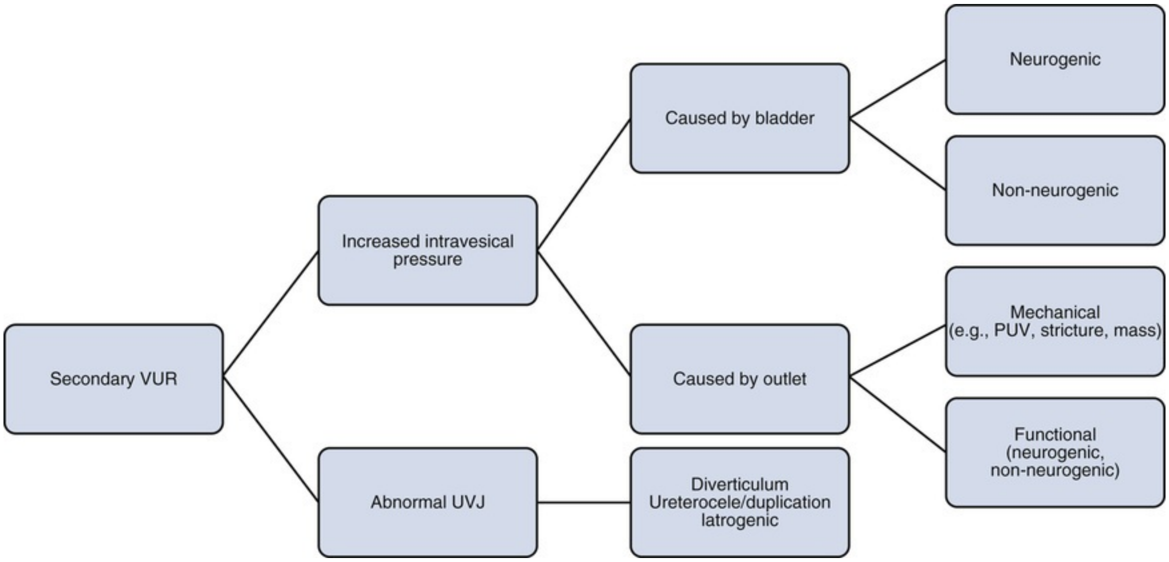
The precise cause of bladder dysfunction is unclear, but may evolve from a persistence of the expected early attempts to suppress bladder contractions during the toilet-training months by volitional contraction of the external sphincter (Allen, 1985). If this behavior becomes prolonged or intensifies, often driven by the child's overwhelming desire for continence, bladder voiding pressures increase. Continence is gradually exchanged for incomplete emptying, resulting in a higher UTI risk. Although investigation of a UTI might diagnose some patients with persistent primary reflux, the elevated bladder pressures gradually distort bladder and UVJ architecture and may create secondary reflux (Koff et al., 1992). Structural failure of the UVJ is likely a critical determinant because high voiding pressures of approximately 100 cm H_2O are common in normal bladders and structurally intact nonrefluxing UVJ. Indeed, with structural failure of the UVJ, reflux occurs at low voiding pressures or during early filling, which is a poor prognostic factor for reflux resolution (Koff et al., 1992; McMillan et al., 2006).

Detrusor overactivity is the most common urodynamic abnormality associated with reflux in neurologically normal children and was found to be as high as 90% in one study of children with voiding dysfunction or idiopathic detrusor overactivity (Glassberg et al., 2010). With regard to VUR resolution in these patients, children with dysfunctional bladders were significantly more likely to exhibit resolution or improvement of reflux (by 2 grades or more) with targeted treatment for the underlying lower urinary tract pathology, with either timed voiding, biofeedback, anticholinergic administration, or alpha blockers (Fast et al., 2013). Overall, 42% of females and 80% of males had complete resolution of VUR with targeted treatments and antibiotic prophylaxis, although this was not statically significant because of underpowering of the study (Fast et al., 2013).

In one study of 37 girls with primary reflux, 75% had overactive detrusor contractions (Taylor et al., 1982). However, the observation that treatment of such patients with oxybutynin can eliminate reflux in up to 80% of involved ureters strongly argues that an overactive bladder frequently can be partly responsible for reflux by either causing secondary reflux or perpetuating primary reflux (Seruca, 1989; Koff et al., 1983; Homsy et al., 1985). One study in 30 children showed concomitant treatment of BBD and use of anticholinergic treatment resulted in complete VUR resolution or a decrease in grade in 70% of the children (Acar et al., 2009). **Thus it is apparent that primary and secondary reflux may not always be mutually exclusive or that what is perceived as primary reflux in some children may, in fact, be secondary to BBD.**

With regard to **abnormalities of the UVJ,** these can arise from either pathology of the ureteric orifice, such as in the case of ureteroceles or with duplication anomalies, or caused by adjacent bladder pathology, such as in the case of a paraureteral diverticulum. Iatrogenic injury to the UVJ can also lead to VUR. Several of these causes are discussed in detail elsewhere in this text.

Regardless of the cause of secondary VUR, in order for clinicians to be able to alter the disease trajectory, a clear understanding of the underlying condition must take place so that a tailored treatment approach to the patient's care can be instituted. See Fig. 29.3 for a simplified algorithm for causes of secondary VUR.



Secondary VUR
Increased intravesical pressure
Abnormal UVJ
Caused by bladder
Caused by outlet
Diverticulum
Ureterocele/duplication
Iatrogenic
Neurogenic
Non-neurogenic
Mechanical (e.g., PUV, stricture, mass)
Functional (neurogenic, non-neurogenic)

FIG. 29.3 Simplified algorithm for causes of secondary reflux.

Clinical Correlates

The previous discussion clearly suggests that multiple opportunities exist for modifying the course of reflux if secondary causes are appreciated, identified, and treated. If VUR is seen as a spectrum of disease with a primary component, which is the innate or biologic predisposition related to patient factors, and the added contribution from secondary elements, which if understood and then treated, the child's trajectory could be sufficiently modified such that once the effects of secondary factors are eliminated, only *true primary* VUR is in fact treated.

Van Gool et al. identified that 18% of children enrolled in the European arm of the International Reflux Study in Children harbored voiding dysfunction associated with more frequent UTIs and greater persistence of reflux compared with those without voiding dysfunction (van Gool et al., 1992).

Similar findings were reported from the Swedish Reflux Trial in which a cohort of children 1 to 2 years of age with grade 3 and 4 reflux were assessed and followed for 2 years for lower urinary tract dysfunction prevalence and type (Sillén et al., 2010). Twenty percent of children harbored some form of dysfunction at entry. The prevalence of bladder dysfunction increased to 34% at 2 years of follow-up. A negative correlation was found between dysfunction at follow-up and reflux improvement ($P = .002$). In addition, scintigraphic renal abnormalities at study entry and at follow-up were also associated with dysfunction (*P* = .001) (Brandström et al., 2010a). Failure to address bladder abnormalities can adversely affect the outcome of antireflux surgery (Koff et al., 1998).

The AUA guidelines (Published, 2010; Reviewed and Validity Confirmed, 2017) suggest that BBD is by far one of the most critical and modifiable variables that affect VUR resolution, overall management, and attendant UTIs (Peters et al., 2010). A meta-analysis now indicates that **BBD is associated with a higher incidence of UTIs while on antibiotic prophylaxis and after surgical correction of VUR, with less VUR resolution at 24 months from diagnosis and with reduced success of endoscopic surgery. In the studies selected by the panel that qualified as having acceptable levels of evidence, BBD did not appear to reduce the success of open surgical reflux correction** (Fig. 29.4).

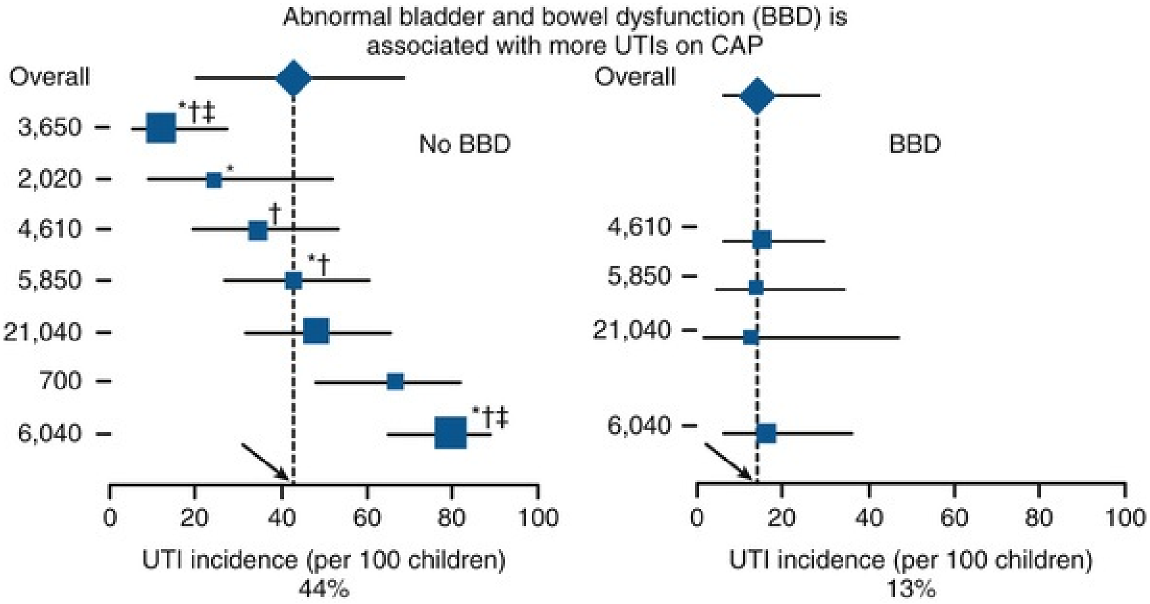


FIG. 29.4 Bladder and bowel dysfunction *(BBD)* and urinary tract infection *(UTI). CAP,* Continuous antibiotic prophylaxis. (From Peters CA, Skoog SJ, Arant BS, et al. Summary of the AUA guideline on management of primary vesicoureteral reflux in children. *J Urol*. 2010;184:1134–44.)

Thus, although BBD is discussed in detail elsewhere in this text, a thorough evaluation of the toilet-trained child with reflux must recognize dribbling, urgency, incontinence, or constipation as symptoms of coexisting BBD. The classic presentation for severe BBD is classic curtsying behavior in girls and squeezing the penis in boys, which acts to suppress bladder contractions. **Constipation often leads to sympathetic, concomitant contraction of both**

anal and urinary sphincters (Grundy and Brierley, 2018) resulting in frequent constipation and encopresis with reflux and UTI. **Constipation must be recognized and eliminated first to establish optimal conditions for successful spontaneous resolution of reflux.** There has been a significant shift in the paradigm for treating children with VUR, ensuring that aggressive treatment of any underlying BBD is addressed. Several studies have demonstrated this link and shown that correcting BBD reduces UTIs in children with VUR (Elder and Diaz, 2013; Santos et al., 2017). A recent study by Shaikh et al. combined data from the RIVUR study (discussed later in detail) and the Careful Urinary Tract Infection Evaluation (CUTIE) study, two large longitudinal studies, and demonstrated the dramatic impact of BBD on the rates of recurrent UTIs in this larger cohort (Shaikh et al., 2016a). The authors showed that in children off CAP, 51% of those with both BBD and VUR experienced recurrent UTIs compared with 20% of those with VUR alone and 35% with BBD alone. Thirty two percent of children with neither BBD nor VUR had UTIs (Shaikh et al., 2016a). Other authors have also shown the close link between BBD, especially constipation, VUR, and recurrent UTIs (Halachmi and Farhat, 2008; Santos et al., 2017; Snodgrass, 1991; Elder and Diaz, 2013; Leonardo et al., 2007; O'Regan and Yazbeck, 1985; O'Regan et al., 1986; Chase et al., 2004).

Urinary Tract Infection and Reflux

The relationships between UTI, VUR, and renal scarring have been historically poorly understood, and management of VUR had focused on surgical correction as the mainstay. Contemporary approaches have shifted from this traditional scheme to focusing initially on the medical management of VUR, surgically treating mostly high-risk patients or those who are refractory or have shown progression. **Reflux is not a general cause of UTI, but is perceived to be a clinical accelerant of upper tract bacteriuria by mechanically delivering infected urine to the renal pelvis** (Peters and Rushton, 2010; Ransley and Risdon, 1979). Infection-related cystitis is expected to incite bladder irritability and dysuria, upsetting the voiding pattern and lowering the threshold for reflux in a given UVJ. In primate studies, surgically created reflux followed by introduction of pathogenic bacteria into the bladder was associated with reflux persistence (Roberts et al., 1988).

In children with dilating reflux, hydroureter and hydronephrosis, in theory, can act as a reservoir for pathogenic organisms to the bladder, and sterilizing the urinary tract may prove more difficult (Blickman and Lebowitz, 1984). Colonized urine might then cyclically reflux retrograde to the upper tracts. Similarly, ureteral atony secondary to the effects of the presence of endotoxin could fail to expel infected urine from the upper tracts, but this does not appear to reduce the ultimate resolution of reflux (Roberts, 1992). Indeed, the dilated upper tracts seen in high-grade reflux explored in the randomized prospectively controlled Swedish Reflux Trial were associated with a 57% rate of recurrent febrile UTI in patients on surveillance without antibiotic prophylaxis (Holmdahl et al., 2010). Reflux correction or antibiotic prophylaxis reduced the recurrent infection rate to approximately 20% ($P = .0001$).

Key Points: Urinary Tract Infection and Reflux

- Reflux is not a general cause of UTI.
- Reflux facilitates pyelonephritis.

Grading of Reflux

Grading systems generally exist to help prognosticate the behavior of the disease they classify. In 1981, the International Reflux Study Committee proposed a grading system for VUR that remains in general use today (Duckett and Bellinger 1982; Lebowitz et al., 1985). **Five grades of reflux are used to depict the appearance of the ureter, renal pelvis, and calyces as seen on the radiographic contrast images generated by a VCUG** (Table 29.3; Fig. 29.5). Using such a system serves several purposes. Grading standardizes the description of the degree of reflux for clinical management of the individual patient and is used for grouping research subjects in the design of clinical studies and trials. Grading facilitates documenting the natural history of the reflux process in the individual patient. It also permits establishing quantitative associations between reflux and other clinical parameters to determine whether such associations hold clinical relevance. Most importantly, describing the initial grade in primary reflux is the most significant parameter associated with prediction of reflux resolution and further serves as an objective means to risk-stratify more appropriately.

TABLE 29.3

International Classification of Vesicoureteral Reflux

GRADE	DESCRIPTION
1	Into a nondilated ureter
2	Into the pelvis and calyces without dilation
3	Mild to moderate dilation of the ureter, renal pelvis, and calyces with minimal blunting of the fornices
4	Moderate ureteral tortuosity and dilation of the pelvis and calyces
5	Gross dilation of the ureter, pelvis, and calyces; loss of papillary impressions; and ureteral tortuosity

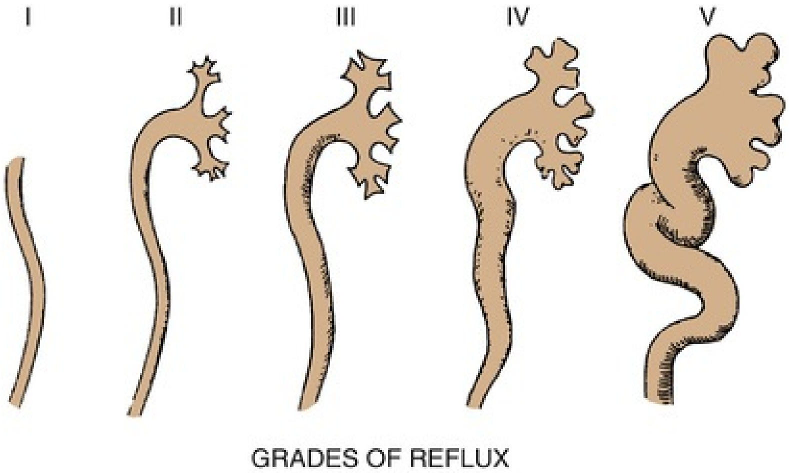

FIG. 29.5 International classification of vesicoureteral reflux.

Despite the widespread use of the five-point grading system, several shortcomings exist. For example, the expected concordance between ureteral and calyceal dilation does not always occur (Fig. 29.6). Either the ureter or the calyces may demonstrate dilation out of proportion to the calyces or ureter, respectively. Whether this reflects an anomaly in the biomechanical tissue properties or peristaltic activity of the excessively dilated ureter, as compared with the typical refluxing upper tract, is unknown. Nevertheless, such anatomy is difficult to grade using the current system.

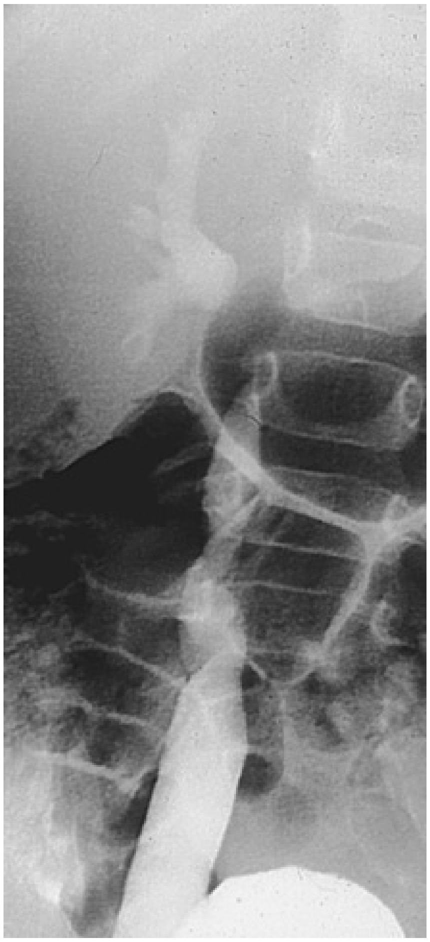

FIG. 29.6 A refluxing ureter with significant dilation of the lower segment but no distortion of the collecting system may be different from the typical system with grade II reflux.

Despite the wide acceptance of this grading system, there is often significant interobserver variability when images are read and grades are assigned. One study, which utilized data retrieved from the RIVUR trial, found that from the 560 left and 524 right ureters graded by a local radiologist and two blinded study reference radiologists, all three agreed on the grade of VUR in only 59% of ureters; two of three agreed on 39% of ureters; and all three disagreed on 2% of ureters. There were higher agreement rates for other VCUG findings such as bladder shape (Schaeffer et al., 2017). A similar finding was reported by O'Neil et al., especially for grades II to IV, although there was reasonable concordance at extremes of grading (O'Neil et al., 2014).

Attempts also have been made to grade reflux using radionuclide cystography (RNC). Because RNC does not provide discrete images of the ureteral and calyceal architecture required to assign reflux grade, classifying reflux by RNC is difficult. Alternative RNC grading has been proposed (Zhang et al., 1987). This provides reasonable concordance to the objectives of the classic grading system by collapsing grades 2 and 3, as well as grades 4 and 5, into low-grade and high-grade reflux, respectively (Fig. 29.7). The clinical impact of this may be noteworthy because, as previously stated, there may be some difficulty in obtaining high interobserver consensus for these grades, and perhaps collapsing the grading system into fewer groupings may be of benefit, although the impact of the reduction in grading detail from five grades (1 to 5) to two (low and high) on understanding reflux pathophysiology and on the design of clinical studies has yet to be determined.

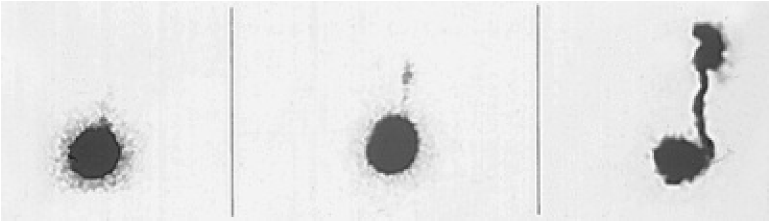

FIG. 29.7 Nuclear voiding cystography showing right-sided reflux. Radionuclide tracer can be quantitated (from left to right) as grade 1 (grade I of the international grading system), grade 2 (grades II to III of the international grading system), and grade 3 (grades IV to V of the international grading system).

Finally, more recent studies have shown the utility of voiding urosonography, which will be discussed in detail later, however no alternate grading system has been proposed. Similar to RNC, grading may likely be more simplified, as detection of the ultrasound contrast with the level of detail seen on traditional VCUG is not yet widespread (Darge, 2010; Kuzmanovska et al., 2017).

Although grading is purely a classification of the appearance of contrast in the upper tract, ascribing an absolute value to the grade has the potential to cast the reflux in unequivocal terms, to the exclusion of other factors that modulate reflux at the time the images are acquired. Inherent bladder dynamics, the bladder outlet, and even ipsilateral UVJ obstruction all influence the degree of reflux at any given assessment (Lebowitz, 1992). Grade, reflux detection, and reflux resolution are all interrelated and are influenced by the degree of bladder filling, the voiding cycle, the number of filling cycles during the contrast cystogram, and whether the reflux occurs during filling or only during voiding. None of these parameters is built into the grading system for reflux used currently. However, given that the principal role of a reflux grading system is to help prognosticate reflux resolution, future incorporation of other parameters may provide additional clinical acumen. Finally, it must be remembered that reflux grade is still presently determined by an imaging study that requires invasion of a sensitive anatomic region. For a given reflux grading result, the variables of bladder dynamics, filling, and voiding cannot necessarily be replicated with certainty in a given patient each time he or she is studied. It is reasonable to speculate that reflux grade could easily vary up or down by at least one grade if sequential studies were performed in a given patient. Thus the entire reflux literature, which historically reports results in terms of five separate grades, must be considered with some circumspection because the veracity of grade at the time of the contrast study may be, to some extent, arbitrary.

Cortical Defects

Congenital Defects Versus Acquired Scar

Previous interpretation of defects seen on renal imaging have been assumed to be scars and sequelae of some presumed condition usually associated with either obstruction or VUR. In a renal context, the term *scar* is most accurately used to describe the fibrous, contracted regions of the kidney that have been destroyed, usually by infection, and often appear as a photopenic area by scintigraphy or, when larger, as hyperechoic and shrunken areas on ultrasonography. The importance of renal scars lies in the realization that they are usually the preventable complication of pyelonephritis, being directly influenced by the presence of VUR in the context of a bladder infection, and when these inciting factors are left unchecked, they can lead to devastating consequences, especially in the pediatric kidney.

Studies have shown the link between VUR, particularly higher grades, and renal maldevelopment that often appears identical to postinfection pyelonephritic scars on ultrasound or renal scans (Murer et al., 2007; Peters and Rushton, 2010; Nordenström et al., 2017a; Yeung et al., 1997; Sjöström et al., 2004; Ylinen et al., 2003). Over time, both in the literature and in clinical practice, the terminology of scarring has become contaminated by the inclusion of reflux-associated congenital dysplasia. However, until such time that primary reflux can be averted prenatally (Gobet et al., 1998) or during the early postnatal phase of continued renal development, dysplasia or reflux nephropathy will remain a nonpreventable sequela of abnormal urinary tract development.

Reflux-Associated Renal Dysplasia

The association of renal maldevelopment with the highest grades of reflux is expected by the theory of Mackie and Stephens, which suggests that an abnormal origin of the ureteric bud will interact suboptimally with the metanephric blastema (Mackie and Stephens, 1975) (eFig. 29.8). This process is believed to be one of the causes of renal dysplasia associated with reflux. Several studies have confirmed the association of VUR and a smaller than normal ipsilateral kidney, an overall reduced relative renal function, and global (Najmaldin et al., 1990; Burge et al., 1992) or focal (Risdon 1993) areas of poor uptake by scintigraphy. These infants tend to be males, and the preponderance of refluxing renal units are grade 4 or 5 (Marra et al., 1994, 2004) (Table 29.4; Fig. 29.9). Indeed, boys tend to be spared an infectious cause of reflux-associated scarring because they have a lower incidence of recurrent UTIs (Capozza et al., 2017; Wennerström et al., 2000). Renal dysplasia is not unique to primary isolated VUR but also may occur in a variety of urologic settings. Duplex renal moieties (Mackie and Stephens, 1975), prune-belly syndrome (Manivel et al., 1989), and PUVs may exhibit reflux-associated renal dysplasia, particularly when the grade of reflux has been high.

TABLE 29.4

Congenital Renal Scarring

GRADE OF VESICOURETERAL REFLUX	NO. PATIENTS NORMAL (%)	SLIGHT DAMAGE (%)	SEVERE DAMAGE (%)
1–3	13 (100)	—	—
4	8 (53)	5 (34)	2 (13)
5	2 (15)	5 (38)	6 (46)

Modified from Marra G, Barbieri G, Dell'Agnola CA, et al. Congenital renal damage associated with primary vesicoureteral reflux detected prenatally in male infants. *J Pediatr*. 1994;124(5 Pt 1):726–730.

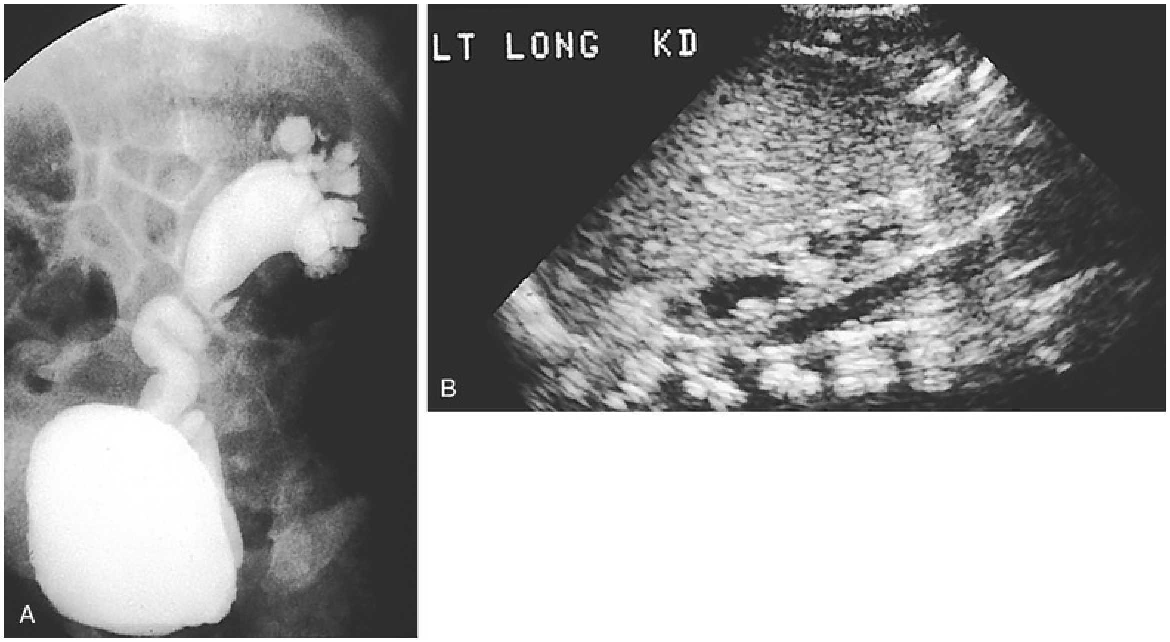

FIG. 29.9 (A) Massive reflux in a boy with antenatally diagnosed hydronephrosis. (B) Ultrasonography demonstrating a kidney with poor internal differentiation. No function was seen on scan.

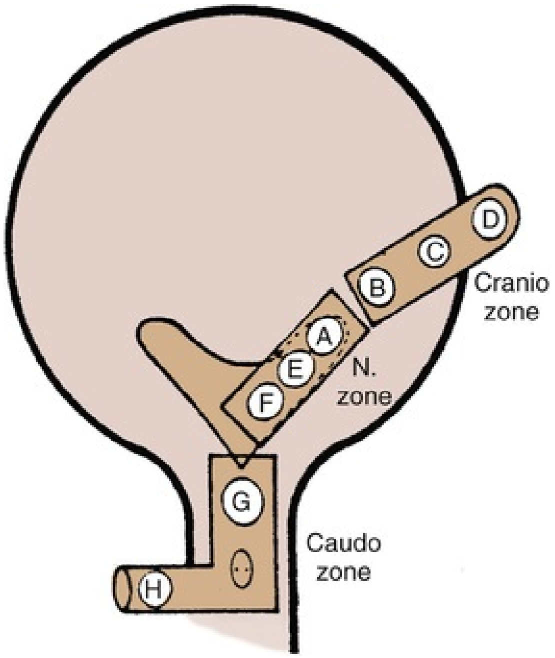

EFIG. 29.8 Classification of ureteric orifice position. Obstruction usually occurs in the caudo zone, and ureters positioned in the cranio zone are likely to result in reflux. Ureters positioned in the normal *(N.)* zone are associated with normal kidneys. Because of ureteric bud abnormality, renal dysplasia occurs with ureters projecting from both abnormal positions. (From Mackie GC, Stephens FD. Duplex kidneys: a correlation of renal dysplasia with position of the ureteral orifice. *J Urol.* 1975;114:274.)

Acquired Renal Scars

It is now firmly established that nephropathy from primary VUR requires the colonization of urine with pathogenic bacteria in the face of normal voiding dynamics. There are specific conditions with VUR and sterile urine that can lead to upper tract damage, however, these usually occur in secondary causes of the reflux, such as in PUVs (Taskinen et al., 2012; Lopez Pereira et al., 2013; Sarhan, 2017). Rare conditions such as congenital megacystis or megacystis-megaureter syndrome can also lead to upper tract damage in the face of sterile urine, but these are exceedingly rare and discussed elsewhere (Kawamura 1977; Burbige et al., 1984; Taghavi et al., 2017). Indeed, the basis of classic medical management of reflux is to maintain urine sterility while allowing reflux to resolve spontaneously. In the absence of infection and secondary causes of VUR producing high storage or emptying pressures, sterile urinary reflux is considered insufficient to cause renal damage. This concept has been most definitively demonstrated by the elegant series of experiments by Ransley and Risdon (Ransley and Risdon, 1981). Reflux was induced experimentally in a pig model by unroofing the intravesical ureteral tunnel. Only if the urine was subsequently infected could pyelonephritis and reflux nephropathy be induced. Without urine infection, no nephropathy could be created (Ransley and Risdon, 1981). Large clinical studies have reiterated these experimental findings, demonstrating new reflux-associated scarring only in children with recurrent UTIs (Smellie et al., 1975; Huland et al., 1984). Animal studies by Hodson et al. that induced reflux and bladder outflow obstruction led to atrophic pyelonephritis, similar to obstructive nephropathy, despite the absence of infection (Hodson et al., 1975). In this model, scarring was intensified by the presence of urinary microorganisms. Thus abnormal hydrodynamic bladder characteristics may modulate even sterile reflux, **but reflux is unlikely to be of any clinical significance in the absence of infection with relatively normal bladder function.** These earlier observations of Hodson, however, **underscore the importance of normalizing bladder and bowel function while awaiting reflux resolution.**

Pathophysiology of Acquired Scarring

Renal scarring is a sequel of infectious pyelonephritis, however, VUR exploits several conditions that predispose to scarring. Most importantly, **reflux provides a mechanical hydrodynamic mechanism that facilitates the ascension of microorganisms from the bladder to the kidneys. Thus reflux may be considered an accelerant for renal tissue infection after bacterial colonization of the bladder.** This principle has been confirmed by studies showing an increased incidence of pyelonephritis in high-grade reflux compared with low-grade reflux (Majd et al., 1991; Alsaywid et al., 2010; McLorie et al., 1990). Furthermore, the frequency of scarring itself appears to be directly proportional to the grade of reflux with which it is associated (Winter et al., 1983; Weiss et al., 1992b). This principle is also supported by observations after reflux correction. In one study of 74 patients in whom preoperative and postoperative scintigraphy studies were available, more than 90% of renal units corrected for reflux showed no new scars during a mean follow-up period of 19 months, despite asymptomatic bacteriuria in 47% of the patients during follow-up (Choi et al., 1999; Leung et al., 2017).

Age

The kidney's predilection for postpyelonephritic scarring is inversely proportional to age. This point is a guiding principle that must be considered in all decisions regarding reflux diagnosis and choice of therapy. The greatest risk for postinfectious renal scarring occurs within the first year of life (Winberg, 1992; Capozza et al., 2017). Similarly, patients younger than 4 years of age are more prone to developing scarring after a single UTI than older children (Garcia-Roig et al., 2018; Sargent, 2000; Smellie and Normand, 1985), though scarring may still occur beyond 5 years of age (Smellie and Normand, 1985; Benador et al., 1997; Sargent, 2000). Indeed, although younger patients are the most vulnerable to scarring, scarring in older children is often the result of late diagnosis, delayed or inadequate treatment of infection, and social factors that often interfere with patient management. Thus, in older children with reflux in whom relinquishing care from the urologist back to the family physician is being considered, it is vital that the child's BBD be completely corrected and the fundamental principles for suspecting and diagnosing UTI and its prompt management be reiterated before transfer (Coulthard et al., 2009; Coulthard, 2002).

The seminal studies of **Ransley and Risdon proposed a "big bang" theory for the origin of scars after infant pyelonephritis** (Ransley and Risdon, 1981)**. They observed that most of the scarring occurs after the initial bout of pyelonephritis and that further scarring in the absence of repeated pyelonephritic episodes is unlikely to occur.** Consequently, the assumption is that little change in the initial scarring pattern is to be expected in follow-up imaging. **However, the uncertainties introduced by such factors as (1) the weakly substantiated assumption that a relatively greater scarring propensity exists in younger kidneys, (2) the reports of new follow-up scarring in the landmark reflux studies (see later discussion), (3) the failure to differentiate between postpyelonephritic imaging defects versus intrinsic developmental dysplasia associated with reflux, (4) the changing appearance of such imaging defects with renal growth over time, and (5) the limited ability to compare different imaging modalities in the reflux literature (ultrasound vs. renal scan) together must challenge the notion that the**

greatest postinfection parenchymal loss occurs after the first infection.

Key Points: Cortical Defects

- Sterile reflux is unlikely to cause scarring.
- The youngest patients are at greatest risk for postpyelonephritic renal scarring.
- Most parenchymal abnormalities are detected after the first episode of pyelonephritis.

Papillary Anatomy

Another factor governing renal susceptibility to scarring is the configuration of the papillae as their ducts open to the calyces. Papillae with a concave architecture (compound papillae) present their ducts at right angles, whereas more convex papillae possess ducts that end obliquely, producing a valvular effect that guards against backflow of urine into the medullary collecting ducts (Fig. 29.10). The more polar calyces are composed preferentially of compound papillae compared with the middle calyces. The former are more commonly the site of intrarenal reflux (reflux into the ducts) and are the prime regions of susceptibility to scarring (Roberts, 1992). Furthermore, necropsy studies have determined that reflux into compound papillae occurs at lower pressures than into simple papillae (Funston et al., 1978). Intrarenal reflux can occur with as little as 2 mm Hg pressure in the neonate (Fig. 29.11). By 1 year of age, the pressure required is one order of magnitude greater (Funston et al., 1978) and helps explain the relative infrequency of intrarenal reflux in older children.

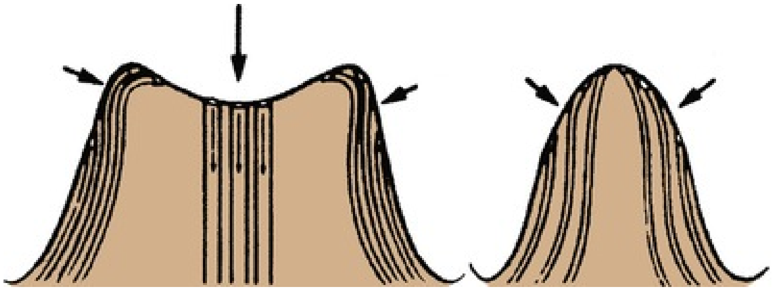

FIG. 29.10 Papillary configuration in intrarenal reflux. A convex papilla *(right)* does not reflux because the crescentic or slitlike openings of its collecting ducts open obliquely onto the papilla. In contrast, a concave *(left)*

or flat papilla refluxes because its collecting ducts open at right angles onto a flat papilla. (From Ransley PG, Risdon RA. Reflux and renal scarring. *Br J Radiol*. 1978;14[Suppl.]:1.)

Bacterial Virulence

Bacteria possess phenotypes that provide infective advantage when exposed to the lumen of the urinary tract. Chief among these is the ability to adhere to uroepithelium. Adherence is mediated by interaction between specific molecules or ligands located on bacterial fimbriae and specific receptors on host uroepithelial cells. A full discussion of the mechanism of action of uropathogenic bacteria is found elsewhere in this text. Once bacteria bind to host epithelium, specific biologic responses are activated in both the microorganism and host cell. Bacterial responses are designed to facilitate their survival and proliferation, as well as inhibit host defenses. These include release of endotoxin and reduction of ureteral peristalsis, which may lead to urinary stasis and reduced antegrade flow of urine. The host inflammatory response perpetuates the classic symptoms of UTI. Although a more systematic understanding of bacterial-host interactions in the propensity for reflux-associated renal scarring is not yet available, it appears that bacteria responsible for postpyelonephritic scars in the presence of reflux often express fewer than three virulence factors (Lomberg et al., 1984). Ironically, then, less virulent bacteria are most often sufficient to produce scarring in the presence of reflux.

Host Susceptibility and Response

Nonhematogenous bacterial access to the urinary tract rests essentially with periurethral organisms. Thus the type and number of vaginal and preputial organisms will determine individual propensity for bladder colonization. Local factors such as hygiene and bowel habits also will influence the bacterial load presented to the perineal surface from the intestinal tract, the latter being the principal repository for organisms that infect the urinary tract. The functional diversity of the host receptors for bacterial adherence also plays a role in the success or failure of bacteria to gain entry to the bladder. In one study, girls with recurrent UTI harbored far heavier periurethral colonization than a control group of girls who were infection free, suggesting a variation in the function of antibacterial defenses in susceptible females (Bollgren and Winberg, 1976). Furthermore, such factors may exhibit both gender- and age-related dimorphism (Bollgren and Winberg, 1976). The great majority of UTIs in both sexes younger than 6 months of age is confined to uncircumcised boys (Rushton and Majd, 1992) and is consistent with the observation that *Escherichia coli* colonization is dense in infant boys but sparse in girls (Bollgren and Winberg, 1976).

Perhaps the greatest tangible factor in promoting susceptibility to UTI is urinary dwell time. The postvoid urine volume is traditionally singled out as being suspect in providing sanctuary for ascending urethral organisms. Perhaps more important, however, is the overall dwell time between voids, which provides the greatest advantage to bacterial proliferation. **When the average doubling time for *E. coli* is measured in minutes, it is self-evident that a quantity of microorganisms sufficient for clinical infection can easily incubate exponentially in a bladder that is not emptied for several hours.**

Advances also have been made in understanding the renal epithelial response to pathogens. The classic components of the innate immune response to infection include activation of the complement system; recruitment of neutrophils and macrophages with scavenging ability; and production of a variety of cytokines, chemokines, and defensins (antimicrobial peptides). One family of receptors, the Toll-like receptors (TLRs), responds to highly constant antigens expressed in bacteria (Chowdhury et al., 2004). The best studied of these, TLR4, detects lipopolysaccharide (LPS). A breakthrough in understanding renal infection came with the demonstration that mutations encoding the *TLR4* gene were responsible for LPS hyporesponsiveness. Nevertheless, molecules accessory to TLR4 are important to its response to LPS. Similarly, molecules such as CXCR1 and CXCR2 are receptors for interleukin-8, the principal renal epithelial secreted chemokine responsible for neutrophil migration. Deficiencies of CXCR expression and function may underlie human susceptibility to pyelonephritis. Such advances placed into the context of VUR provide interesting and powerful opportunities to modify the natural history of the condition.

As well as orchestrating the assembly of the phagosome for bacterial clearance, **the fallout of these renal epithelial processes that is the inflammatory response leads to local tissue damage and scarring.** Hallmarks of the response include capillary congestion, ischemia, reperfusion injury, and free oxygen radical and inflammatory cytokine release (Roberts, 1992). Microabscess formation later coalesces into scar tissue typical of the histologic changes of chronic pyelonephritis (Roberts, 1992). Although limiting the inflammatory response to reduce scarring may appear logical, no specific pyelonephritis anti-inflammatory pharmacotherapy is yet available. Traditional nonspecific anti-inflammatory agents, both steroidal and nonsteroidal, are not currently indicated in the treatment of pyelonephritis; in their current formulations, the latter pose a threat to renal function. Nevertheless, the concept has been demonstrated experimentally in animals. A full understanding of the specific pathways involved in reflux-associated pyelonephritis could provide key strategies to limiting specific renal inflammatory fallout without limiting bacterial clearance. Until then, antimicrobial therapy instituted in a timely fashion, usually within 24 to 48 hours, is the single most effective pharmacologic strategy to date to limit the scarring consequences of pyelonephritis in both young and older children (Ransley and Risdon, 1981).

Hypertension

VUR has long been held as a primary cause of significant hypertension in children. Arterial derangements in the renin-angiotensin system and sodium-potassium adenosine triphosphatase activity (Goonasekera et al., 1998) may be involved, although the precise pathophysiologic process is not clear. Although methodologic flaws (Farnham et al., 2005) taint many studies of hypertension in the pediatric urology population, one study using continuous ambulatory blood pressure monitoring revealed some correlation between progression to hypertension and more severe reflux nephropathy in children (Lama et al., 2003). An adult review of 157 patients with hypertension, but no evidence of abnormal renal parameters, discovered latent VUR in 20% of the subjects on cystography, demonstrating that a significant association between reflux and hypertension exists in adulthood (Barai et al., 2004). The striking association between VUR diagnosed for the first time only in adulthood and arterial hypertension continues to underscore the importance of remaining vigilant about untreated infections in the reflux population (Kohler et al., 1997). Nevertheless, it remains unclear whether it is the nephropathy associated with postinfection scarring, congenital dysplasia associated with reflux, or some combination of both that predisposes to hypertension (Wolfish et al., 1993). This latter observation questions whether prevention of postinfection scarring per se in the management of VUR will specifically help offset future hypertensive risk in cases in which congenital renal dysplasia is already present. There is obvious potential for the cause of reflux-associated hypertension to rest with deranged renal microvascular mechanisms associated with parenchymal defects. This suggests that successful correction of reflux alone is unlikely to ameliorate blood pressure (Wallace et al., 1978). Indeed, removal of renal segments verified by selective renal vein sampling of arteriolar or segmental vessel renin levels has provided durable normalization of blood pressure in carefully selected patients (Tash et al., 2003) with up to 67% of patients becoming normotensive after nephrectomy (Schlomer et al., 2011). On occasion, complete removal of a small unilateral congenitally dysplastic or globally scarred and shrunken kidney also may correct renovascular hypertension (Dillon and Smellie, 1984; Schlomer et al., 2011) because such kidneys are clearly not amenable to partial nephrectomy for any discrete segment.

Renal Growth

Several studies have attempted to demonstrate that correction of reflux will restore retarded renal growth associated with reflux, particularly when the growth defect is in a unilaterally affected kidney. However, reflux correction is a poor predictor of catch-up growth in such kidneys (Hagberg et al., 1984; Shimada et al., 1988). A significant factor governing growth of an ipsilateral kidney is the function of its contralateral mate. Although forestalling infection in the presence of VUR will maintain the normal trajectory of renal growth in most cases (Edwards et al., 1981), it must be remembered that compensatory hypertrophy of the contralateral kidney will magnify the perceived impact of infection on renal growth because the contralateral developing kidney will generally assume the required renal function whenever the ipsilateral kidney is unable to contribute optimally to function. When reflux correction has been associated with improved renal growth, it is likely this is caused by removal of the propensity for ascending infection rather than the elimination of the reflux per se (Willscher et al., 1976a, 1976b; Beetz et al., 1991).

Renal Failure and Somatic Growth

Today, with modern management, renal failure resulting from primary VUR-associated infection should be nonexistent, yet it is still rarely seen. This is largely caused by the virtual paradigm shift in reflux management championed by Smellie et al. during their pivotal studies of reflux and infection in children during the 1970s and 1980s. Over the past 30 years, chronic pyelonephritis as a primary cause of end-stage renal disease has fallen from 25% to 15% (Advisory Committee to the Renal Transplant Registry, 1975) to less than 2% (Meiland et al., 2007; Geerlings 2016; NAPRTCS, 2004). Reflux nephropathy in all its forms, however, was the second most common primary diagnosis in non-black pediatric transplant recipients. In a registry of children on renal replacement therapy (RRT) in Australia and New Zealand, reflux nephropathy was the primary diagnosis for 13.6% of children (Craig et al., 2000) and the second leading cause for initiation of RRT after glomerulonephritis (Orr et al., 2009). The incidence has changed somewhat, but this may reflect a shift in diagnosis from nephropathy caused by VUR to congenital dysplasia (Orr et al., 2009).

The medical renal disease (Hinchliffe et al., 1994) that accompanies renal scarring can include hyperfiltration, concentrating defects, proteinuria, microalbuminuria (Lama et al., 1997), renal tubular acidosis (Guizar et al., 1996), and increased fractional excretion of sodium and magnesium. Although all of these parameters are likely the direct result of tubular and parenchymal damage or dysplasia, concentrating defects and increased concentrations of tubular enzymes (Carr et al., 1991) have been reported in the presence of sterile reflux, independent of any history of infection per se (Walker et al., 1973). The concentrating defect is proportional to reflux grade and improves after reflux cessation. These observations have suggested that a relative flow resistance may be created by retrograde nature of reflux and raises the possibility of a functionally obstructive parameter in reflux pathogenesis. However, the precise relationship between antegrade flow, retrograde flow, and bladder dynamics has not been more fully articulated.

One of the best global parameters of renal function in children is the somatic growth curve. Many children with VUR fall below the normal age-adjusted growth curve, particularly in patients with bilateral reflux and some degree of renal damage. Furthermore, successful suppression of pyelonephritis through either medical prevention of infection or surgical correction of reflux itself can result in catch-up growth, both for height and weight (Polito et al., 1997, 1996). Although a clear superiority has yet to be demonstrated between medical and surgical therapy to affect growth improvement or subsequent renal scarring after an initial pyelonephritic insult, surgical correction of reflux can benefit somatic growth when recurrent BUTI indicates failure of antibiotic prophylaxis (Sutton et al., 1989).

Diagnosis and Evaluation of Vesicoureteral Reflux

Confirmation of Urinary Tract Infection

Acquired reflux nephropathy can be a potentially catastrophic condition with significant, yet potentially preventable aspects. If certain risk factors are addressed and eliminated, damage to the upper urinary tract can be lessened and even prevented entirely. Upper tract scarring in the context of VUR is a combination of several factors, however, one of the most important is the presence of infected urine. When present in the lower urinary tract, bacteria can more easily ascend to involve infection of renal units. Because preventable reflux nephropathy is predicated on the combined effects of UTI and reflux, confirming and documenting true UTIs is paramount in the initial appropriate management of the patient with reflux. Many variables are responsible for the accurate assessment and interpretation of urine studies in the context of reflux. These include clinical history and presence of fever; age of the patient; method of urine specimen collection, storage, and delivery; circumcision status in males; and the results of urine dipstick and microscopic analyses. Confirming true pyuria by dipstick or microscopic analysis, in addition to the presence of bacteriuria, will help to differentiate infection from contamination.

The importance of obtaining an appropriately collected urine specimen cannot be overemphasized. In infants, oftentimes caused by parental and clinician discomfort, a urine specimen collection will often entail the placement of an adhesive urine bag over the genitalia. Unfortunately, routine practice is so variable that such guidelines are often difficult to follow or confirm, and **microbial contamination of bagged specimens is common. Conversely, this method is most useful for establishing the presence of pyuria or if the resulting urine culture is negative.** Although fevers are common in infants, UTI composes only 5% of children presenting with fever (Hoberman et al., 1997). Thus the ability to easily rule out a UTI in the febrile infant with reflux facilitates management. If there is a high clinical suspicion for UTI in an infant, the more accurate method is to obtain a catheterized specimen. Even this method may prove suspect in the uncircumcised infant whose preputial skin is not yet retractable to easily reveal the urethral meatus. In this and other instances in which the urethral route is difficult or compromised in patients of any age, some also advocate for suprapubic aspiration, which provides the most accurate method of obtaining a urine sample, in children who cannot provide a midstream urine specimen (Subcommittee on Urinary Tract Infection, Steering Committee on Quality Improvement and Management, and Roberts, 2011). Although this technique has limited risks, particularly if guided by ultrasonography, technical expertise and experience are required, and many parents and physicians perceive the procedure as unacceptably invasive. In males with severe phimosis and girls with significant labial adhesions, it may be the only reliable means to obtaining an uncontaminated urine specimen (Subcommittee on Urinary Tract Infection, Steering Committee on Quality Improvement and Management, and Roberts, 2011).

In the younger child, however, repeated catheterization for specimen acquisition and radiographic assessment should be considered carefully. This routine practice is coming under greater scrutiny as the long-term sequelae of repeated catheterizations has become appreciated (Stashinko and Goldberger, 1998) and could become a factor in patient compliance with follow-up.

In patients who can void spontaneously, a clean voided midstream-catch specimen is adequate (Subcommittee on Urinary Tract Infection, Steering Committee on Quality Improvement and Management, and Roberts, 2011). The initial urine is discarded because it can be rich in periurethral organisms.

Attention to these details cannot be overemphasized as major management decisions, including operative intervention to correct reflux, often rest solely on a diagnosis of UTI. Conversely, confirming microbial growth in a urine specimen is of little value if the mode of collection is highly suspect and likely to harbor contamination. Again, confirmation of UTI begins with collection of the urine specimen. If storage is necessary, specimens should be maintained at 4°C until transfer to the laboratory. Keeping in mind that in children who are not toilet trained, a bagged specimen is of little use, unless negative, as contamination rates can be quite high with associated high false-positive rates (Sørensen et al., 1988; Subcommittee on Urinary Tract Infection, Steering Committee on Quality Improvement and Management, and Roberts, 2011; Springer and Subramaniam, 2014; Selekman et al., 2016). Urine should be collected via midstream catch in children who are toilet trained and with a retracted foreskin in males who are uncircumcised. **Finally, it is important to reiterate that urine culture results cannot be accurately interpreted without reviewing the urine analysis and evaluating the overall clinical picture.**

Key Points: Diagnosis and Evaluation of Vesicoureteral Reflux

- The method of urine collection and the presence of pyuria are of utmost importance in the diagnosis of UTI to avoid false-positive culture results.
- The gold standard study for the diagnosis of reflux requires bladder catheterization.
- Nuclear cystograms, though more sensitive, provide much less anatomic detail than does a VCUG.
- Parental perceptions of reflux management must be considered when treating a child with reflux.
- Upper tract assessment is based on serial studies.
- The challenge in imaging is to differentiate congenital reflux–associated renal dysplasia from scarring acquired after infection.

Evaluating Urinary Tract Infection

Numerous factors may trigger the search for reflux in the patient after one or more UTIs. The probability of finding VUR in children with a UTI varies depending on the study of interest, but the rate centers around 30% (Sargent, 2000). Furthermore, in some patients, higher grades of reflux may be associated with various degrees of existing renal parenchymal maldevelopment, or dysplasia (Nakai et al., 2003; Farhat et al., 2000). In addition, because reflux tends to resolve over time, it is reasonable that UTI is more commonly associated with reflux in younger patients (Smellie et al., 1981; Capozza et al. 2017).

As the basic evaluation for children with a history of UTI and suspected VUR inevitably involves some form of invasive testing or subjects children to some form of radiation, there is tremendous push to limit the intrusive and often traumatic experience for both parents and children, when possible.

It is the position of the authors that a risk-stratified approach be taken to optimally evaluate and manage each patient in the diagnosis and evaluation of children with suspected VUR. This does not preclude a basic approach to the evaluation of children with UTIs, but reinforces the need to view VUR less as a dichotomous condition and more as a spectrum of disease greatly affected by both the degree of underlying severity, innate patient risk factors, risk for morbidity from repeat infection, and invasiveness of treatment.

Because of the higher incidence of renal scarring in patients with VUR and repeat UTIs (de Bessa et al., 2015; Wang et al., 2015; Nagler et al., 2011; Peters et al., 2010), most approaches for the evaluation of children with repeat UTIs prompt some form of workup to rule out VUR (Fig. 29.12). However, the current state of the VUR debate makes it difficult to predict which evaluated patients might harbor clinically significant reflux, given how common UTIs are in children, although some reassurance can be provided when a voiding study is negative for VUR.

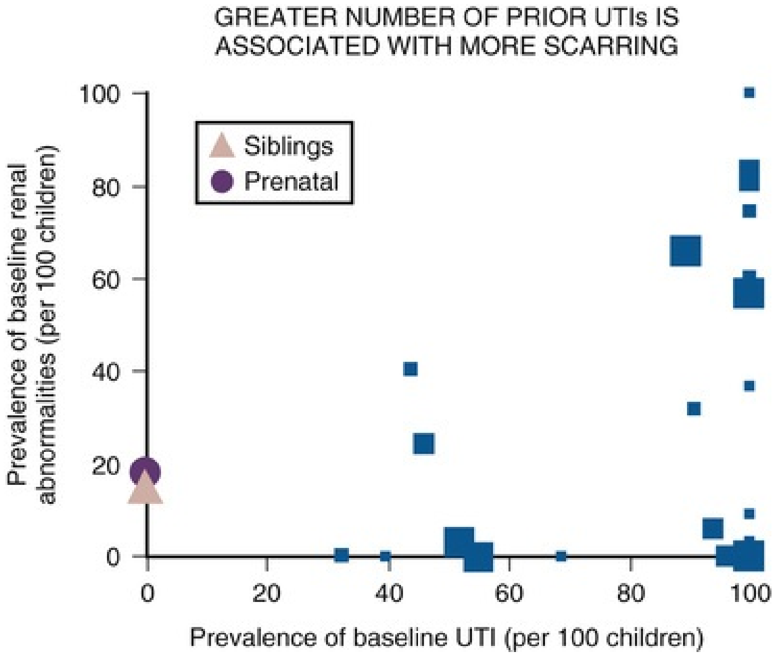

FIG. 29.12 Urinary tract infection *(UTI)* history. (From Peters CA, Skoog SJ, Arant BS Jr, et al. Summary of the AUA Guideline on Management of Primary Vesicoureteral Reflux in Children. *J Urol.* 2010;184(3):1134–1144.)

There is also parental concern over the invasiveness of VCUG and the need to include it as part of the initial diagnostic workup. This occasionally limits the initial diagnostic workup to ultrasonography only, which may help rule out any significant gross structural defects. This is also in keeping with guidelines released from the **American Academy of Pediatrics (AAP), which recommend ultrasonography in children younger than 2 years of age with a first febrile UTI as the initial diagnostic test, delaying a VCUG unless there are significant findings on ultrasonography** (Subcommittee on Urinary Tract

Infection, Steering Committee on Quality Improvement and Management, and Roberts, 2011). Thus, taking the appropriate voiding, fever, and family histories into account, ultrasonography of the bladder and kidneys can be considered a reasonable minimum in evaluating the infant or child after a UTI. Even the detection of reflux after treatment for UTI could be of questionable significance if the child is older and/or if no fever accompanies the UTI. On the other hand, the presence of structural renal anomalies or significant asymmetry in renal size, ureteral dilation, or bladder anomalies would support proceeding with a VCUG (Subcommittee on Urinary Tract Infection, Steering Committee on Quality Improvement and Management, and Roberts, 2011; The National Institute for Health and Care Excellence, 2018).

The advent of prenatal ultrasonography has likely augmented the detection of asymptomatic reflux in newborns as a result of surveillance for persistent postnatal hydronephrosis and the ensuing performance of cystography in these infants. It must be remembered that the sonographic finding of primary hydronephrosis is generally much more common than dilation caused by active reflux at the time of ultrasonography. Indeed, there is little correlation between the degree of antenatal hydronephrosis and the presence and grade of reflux (Phan et al., 2003; Farhat et al., 2000). A corollary study also demonstrated normal postnatal sonograms in 25% of patients with VUR and antenatal hydronephrosis (Lebowitz, 1993).

Assessment of the Lower Urinary Tract

Cystographic Imaging

The basis of reflux detection lies in demonstrating the retrograde passage of an imaging contrast material from the bladder to the ureter and renal pelvicalyceal system. The currently available methodologies require a source of contrast agent in the bladder. The two approaches, the indirect and direct cystograms, can be performed depending on whether the contrast enters the bladder indirectly after excretory urography or directly, usually by urethral catheterization. Indirect cystography, although avoiding the invasive nature of urethral catheterization, is prone to false-positive interpretation as a result of contrast that does not originate from the bladder remaining in the ureter or pelvis after filtration and antegrade passage and false-negative results in lower grades of reflux (Conway et al., 1975). However, it has been suggested that the value of indirect cystography may lie in ruling out the presence of VUR (Carlsen et al., 1986).

The VCUG is a fluoroscopic study that provides information on both the functional dynamics and structural anatomy of the urinary tract. The detailed technique of the VCUG is discussed more fully elsewhere in this text. Bladder contrast is instilled by gravity after urethral catheterization at a maximum height of 70 cm of water (Lebowitz et al., 1985). Bladder capacity is recorded when contrast influx ceases. Static images record bladder contour, presence of diverticula or ureteroceles, volume at which reflux occurs, grade of reflux, configuration and blunting of calyces, and intrarenal reflux, if present. Passive or active reflux is demonstrated dynamically during fluoroscopy while filling and voiding, respectively. In addition, bladder neck anatomy, funneling or dilation, and urethral patency are parameters derived from the VCUG. Delayed or postvoid films are crucial in documenting clearance of contrast from the upper tracts because retained contrast, particularly with dilated pelvicalyceal systems, could signify the presence of a concomitant UPJ obstruction (UPJO), either primarily or secondarily as a result of distortion of the UPJ by massive retrograde filling of the pelvis by the reflux (Hollowell et al., 1989). Care should also be exercised in the child with dilating reflux on a VCUG when there is significant contrast dilution in a dilated ureter. One should consider the presence of concomitant UVJ obstruction in the context of VUR when some or all of the following are seen: (1) dilated proximal ureter/not necessarily kidney, (2) transition area to distal, aperistaltic juxtavesical segment, (3) decrease in contrast caused by mixing with trapped, nonopaque urine, and (4) delay in drainage on postvoid film above aperistaltic distal ureteral segment (Blickman and Lebowitz, 1984).

These may suggest some form of delayed drainage at the UVJ, which could represent possible obstruction, and care should be exercised in these cases.

The VCUG and RNC are the two common forms of direct cystography and constitute the present-day gold standard approaches to reflux detection. More recently, to eliminate the need for ionizing radiation, some studies have demonstrated a growing interest in sonographic detection of reflux using either color Doppler imaging (Valentini et al., 2001; Galia et al., 2004; Castagnetti et al., 2006) or echo-enhancing contrast agents (Berrocal et al., 2001; Darge et al., 2001, 2002; McEwing et al., 2002; Valentini et al., 2004; Ntoulia et al., 2018; Piskunowicz et al., 2016). Modern transducers coupled with the use of echo-enhancing contrast agents can image reflux well in children with comparable results to traditional VCUG, especially when using new techniques and second-generation enhancing agents (Kuzmanovska et al., 2017; Piskunowicz et al., 2016; Valentini et al., 2001; Ntoulia et al., 2018; Castagnetti et al., 2006; Darge, 2008a, 2008b, 2010; Riccabona et al., 1993).

The RNC uses a radionuclide tracer labeled with ^{99m}Tc pertechnetate and scintigraphy to detect reflux. Indirect RNC is performed through passive filling of the bladder after intravenous injection and passage of tracer into the bladder is achieved (Gordon et al., 2001). This requires that children be toilet-trained. Children are instructed to void, and images are captured to detect reflux, if present. Direct RNC utilizes directed filling of the bladder with a catheter, similar to VCUG (Fettich et al., 2003). RNC has historically enjoyed a reputation for requiring approximately 1% the radiation exposure generated by the continuous fluoroscopy VCUG and 10% of that for pulsed fluoroscopy VCUG (Ward et al., 2008; Blaufox et al., 1971; Diamond et al., 1996), and for indirect RNC, the need for catheterization is avoided altogether. Presently, the reduced radiation exposure of modern digital techniques has significantly narrowed the difference between fluoroscopy and RNC, especially when certain refinements are employed. Although less anatomic detail is traditionally afforded by the RNC, newer techniques have been able to increase both its sensitivity and specificity. For indirect RNC, this includes data captured during failed voids, adding extra imaging sequences at intervals during bladder filling and by using simple mathematical criteria to determine if VUR was present when visual imaging results were equivocal (Keir et al., 2013). Sensitivity and specificity for indirect RNC has been noted in the literature to be 70% to 74% (Gordon et al., 1990; Keir et al., 1998) and 90% (Gordon et al., 1990), respectively. Direct RNC has shown good correlation with VCUG for VUR (Unver et al., 2006), and certain studies have shown techniques that track bladder volume during filling to further help define the grade of reflux, something that has been a major criticism of this imaging modality (Agrawal et al., 2009).

Although traditional grading of VUR with RNC has been difficult, it can be an ideal imaging study to both screen and monitor the natural history or surgical follow-up of reflux. In contrast with the VCUG, the instilled bladder contrast material itself is the radiation source. Reflux is detected on scintigraphic gamma camera images (Fig. 29.13). Lack of confounding imaging densities typical of fluoroscopy and the ability to obtain prolonged exposures allow for greater sensitivity of the RNC in grade 2 to 5 reflux. Ironically, grade I reflux into the distal ureter is often poorly detected because of the overlying exposure generated by contrast within the bladder. Bladder volume grading has been a useful technique to improve on this. This involves filling the bladder with small infusions of saline mixed with radionuclide tracer, usually at a rate of 10% of the estimated bladder capacity, and noting the volume when reflux is first seen on scintigraphy. Several images are captured, including a 30-second anterior prevoid static image, a voiding dynamic set, and an anterior postvoid static image (Agrawal et al., 2009). As the volume when reflux is first seen has been shown to be a useful measure in understanding overall reflux severity and may affect spontaneous resolution rates (Weiss et al., 1992a; Polito et al., 2000), the use of this technique may offer augmented prognostic measures for children with VUR. Thus RNC and VCUG imaging can be used complementarily, balancing radiation exposure with the need for dynamic information and anatomic detail. Notwithstanding the previous discussion, modern digital fluoroscopic equipment has further reduced the radiation exposure of conventional fluoroscopy, thereby narrowing the difference in radiation exposure between the two modalities (Fettich et al., 2003; Ward et al., 2008; Diamond et al., 1996; Blaufox et al., 1971; Jaju et al., 2015; Linke et al., 2016).

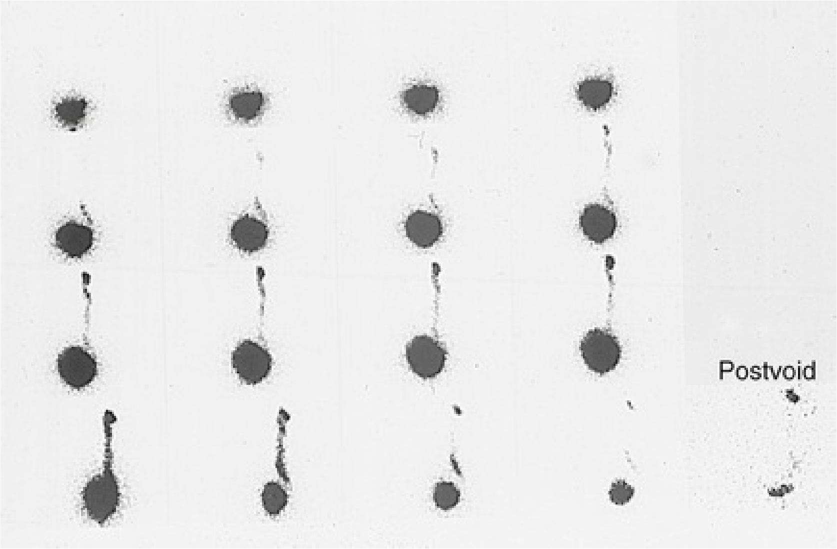

FIG. 29.13 Radionuclide cystogram showing right-sided reflux that worsens with bladder filling. The upper collecting system drains fully with voiding.

Direct imaging of reflux is affected by several parameters. These include bladder contraction during voiding, the volume instilled into the bladder, presence of infection, and therefore inflammation of the UVJ mucosa. Reflux may occur during filling or only during active bladder contraction associated with voiding. Consequently, if a patient is unable to void in the artificial setting of the radiography suite, false-negative results may ensue if reflux is present during the high pressure portion of the test associated with voiding. More importantly, even during voiding, reflux may not be demonstrated on a single filling-voiding cycle. Several studies have demonstrated a roughly 12% to 20% greater detection rate for VUR if a cyclic study is performed (Paltiel et al., 1992; Papadopoulou et al., 2002; Novljan et al., 2003). A cyclic VCUG involves a second or third cycle of bladder filling and emptying under fluoroscopic observation. To limit the overall exposure to ionizing radiation, there may be a role for cyclic VCUG without the real-time fluoroscopy, limiting the amount of images acquired and standardizing image capture at several time points during a three-cycle study without significantly compromising the overall information garnered during the study (Kadioglu et al., 2006). Cyclic RNC has also been employed as a diagnostic strategy (Fettich and Kenda, 1992).

Reflux may also be demonstrated during catheter filling of the bladder. Because filling assumes far lower intravesical pressures than that of voiding, unless there is active detrusor overactivity, reflux during filling and passive reflux along with grade are generally considered poor prognostic signs for future reflux resolution (Lee et al., 2016). Early reflux during filling can be a common finding in patients with acquired or neurogenic voiding dysfunction, wherein high-resistance voiding gradually remodels the bladder wall and UVJ, leading to complete failure of the latter's antireflux mechanism and reflux at low volumes of the filling phase (Koff, 1992). This is in contrast with reflux that occurs only during the higher pressure voiding phase of bladder emptying. Moreover, technical inconsistencies can lead to variations in rates of reflux detection: if the bladder is underfilled, reflux may be underdetected.

One difficult dilemma in the performance of voiding studies involves cystography during active infection. The primate work by Roberts showed that in the presence of bacterial infection, there is decreased peristalsis with subsequent ureteral dilation and decreased drainage, which can help explain this phenomenon (Roberts, 1992). On the other hand, evoking reflux during active cystitis, by definition, will transmit bacteria to the upper urinary tract and renal pelvis and risks iatrogenic pyelonephritis. Nevertheless, the general consensus has been to delay the voiding study for at least 1 week or longer to allow for adequate recovery from the acute infection episode (Craig et al., 1997), although there have been several studies that show little difference in delaying the diagnostic workup and note that ensuring the urine is sterile and that the child has clinically improved with treatment is necessary before a VCUG is obtained (Golmakani et al., 2016). If it is imperative to make the diagnosis of reflux in children with a history of recurrent pyelonephritis and repeatedly negative voiding studies in the intercurrent periods, cystography during UTI should be considered, particularly if family compliance with follow-up is uncertain.

Cystoscopy and the Positioning of the Instillation of Contrast Cystogram

Modern management of reflux does not include routine cystoscopy. It is rare for cystoscopy to add any information that will alter management of a patient with reflux, either at the time of initial diagnosis or during follow-up. Its use, especially in children with UTI or reflux, should be considered only exceptionally. Similarly, the appearance and configuration of the ureteric orifices and intramural tunnel length that are afforded by cystoscopy and once considered useful parameters have over time provided little correlation with either the diagnosis or grade of reflux (Duckett, 1983). Cystoscopy can provide useful information immediately before open surgery, such as evaluation of orifice position, duplication anomalies, and the proximity of diverticula to the orifice, and confirm the absence of mucosal inflammatory changes and urethral patency if indicated.

In a select group of patients who present with recurrent febrile UTIs and no evidence of VUR on VCUG, there is some evidence to suggest that the positional instillation of contrast (PIC) with fluoroscopy may have some benefit.

The technique of PIC cystography involves cystoscopy while the child is under anesthesia. With the bladder empty, the cystoscope beak is positioned close to and facing the ureteric orifice. Contrast is instilled at the ureteric orifice using the irrigation port of the cystoscope from a height of 1 meter above the bladder. Fluoroscopic spot imaging is done simultaneously with the instillation. PIC-VUR is confirmed if retrograde flow of contrast into the ureter/kidney pelvis is observed. The bladder is emptied before the procedure is repeated on the contralateral side.

Several studies have shown occult reflux using PIC cystography (Rubenstein et al., 2003; Hagerty et al., 2008; Cheng 2009; Tareen et al., 2006) and a reduction in recurrent UTI rates after successful medical or surgical management in these children (Cheng 2009; Palmer et al., 2011; Matsumoto et al., 2011).

It is conceivable that the antireflux mechanisms may be less robust in some patients with recurrent UTI. The unique, but unphysiologic, nature of the PIC technique may then reveal reflux in such cases. Furthermore, PIC cystography does not allow for age-adjusted instillation pressures; some pressures may be too high in younger patients and may be creating iatrogenic reflux rather than unmasking relevant, physiologically borderline reflux.

A multi-institutional study by the PIC Cystography Group (Hagerty et al., 2008) examined the clinical significance of reflux discovered by PIC in 118 children with a history of febrile UTIs and negative VCUGs. VUR diagnosed by PIC was treated by surgery (endoscopic injection in 104 patients, reimplantation in 3) or by antimicrobial prophylaxis (11 patients). In the 98 evaluable patients, VUR grade was 1 to 3 and was unilateral in 34 patients and bilateral in 64 patients. Treating occult VUR identified by PIC cystography, with either antibiotics or surgery, reduced the incidence rate of febrile UTI by 20-fold (from 0.161 per patient per month before PIC-VUR treatment to 0.008 per patient per month after treatment). In another study, there was also a statistically significant association between PIC-VUR grade and severity of renal scarring on ^{99m}Tc dimercaptosuccinic acid (DMSA) scans (Berger et al., 2013).

It is generally believed that VUR does not cause UTI; however, in this nonrandomized study (with the patients acting as their own controls), PIC cystography provides some evidence and rationale for antireflux therapy in a very limited subset of patients.

Although some data have shown that a role for PIC cystography may exist in the evaluation of the patient with multiple UTIs, it should not be used as a first-line diagnostic tool, because a general anesthetic is necessary. Rather, it should be reserved for a very select group of patients who pose rare, diagnostic dilemmas. **Until prospective studies randomizing patients with PIC-VUR to treatment or observation to confirm its clinical benefit are performed, its role remains very limited.**

Assessment of the Upper Urinary Tract

Rationale for Serial Assessment of Upper Tracts

The known effects of VUR on the upper tracts are largely what direct the need for reflux diagnosis and correction. Pyelonephritis propagated by reflux causes renal scarring, impedes attainment of full renal growth potential, and increases the risk for renovascular hypertension (Mattoo et al., 2016; Rushton et al., 1992; Willscher et al., 1976b; Schlomer et al., 2011). Therefore, imaging of the upper tracts is directed at assessing renal structure and function, with attention to the aforementioned parameters. A fundamental goal in upper tract imaging with VUR is to ascertain whether abnormalities are caused by ongoing or resolved reflux and differentiate them from congenital dysplasia, medical renal disease, or hydronephrosis. Almost always, particularly in the youngest patients in whom VUR has the greatest potential to cause renal injury, these goals are best achieved through serial imaging of the kidneys over a period of months to years.

Many observational studies raised concern for the sequelae of UTIs and highlighted the potential for successful intervention. Reflux status**, coupled with the age of the patient, sex, race, family history of reflux, and bladder and bowel functional status, serve as a guide to selective imaging, which attempts to balance intensity of imaging studies with propensity for renal damage.**

Renal Sonography

RBUS is noninvasive, is performed relatively quickly, and does not require intravenous access for contrast agents, which makes it ideal for initial evaluation. It is, therefore, the initial mainstay of renal imaging in VUR management. As a nonionizing, noninvasive imaging platform, coupled with its ability to assess renal vasculature, it is also ideal for serial follow-up of the kidneys.

Ultrasonography lends itself well to quantitative assessment of renal dimensions (Rodriguez et al., 2001; Chen et al., 2002), which then can be used to follow renal growth over time. Renal growth can be referenced to standard renal growth curves. In reflux diagnosed in the neonatal period, baseline renal dimensions are obtained, and appropriate renal growth can be monitored. The impact of any intercurrent febrile UTI can be gauged by observing the effects on renal growth, which is impacted significantly as the number of infections increases (Parvex et al., 2008). Similarly, if the UTI history between follow-up visits for reflux is unclear, serial assessment of renal size can help the urologist advise on the need for further assessment of renal function by scintigraphy or on the need for reflux correction. Indeed, in the presence of reflux, modern postnatal renal sonography provides excellent correlation between renal length and scintigraphic hypoplasia (Farhat et al., 2002a, 2002b).

Ultrasonography is also useful for evaluation of renal corticomedullary differentiation. Loss of corticomedullary differentiation, or an increase in overall echogenicity of the kidney, is associated with some degree of renal functional impairment (Chi et al., 2006; Stember et al., 2016). In neonates, in particular, these parameters can be useful in assessing the overall status of a renal unit in the context of higher grades of reflux, even before any history of UTI or pyelonephritis has occurred. Coupled with a relatively smaller ipsilateral kidney, loss of corticomedullary differentiation or increased echogenicity suggests a degree of intrinsic renal dysplasia that developmentally accompanies high-grade reflux (Chi et al., 2006). In the neonate with no infection history, such findings should not be confused with acquired renal scarring caused by pyelonephritis.

Notwithstanding the value of renal sonography, it must be remembered that the RBUS cannot diagnose VUR. Although it is tempting to speculate on the presence of reflux with postnatal hydronephrosis, particularly of higher grades, there is no significant correlation between a normal sonogram and the absence of reflux (Farhat et al., 2000; Zamir et al., 2004). Similarly, renal sonography is limited in its ability to visualize minor renal cortical abnormalities. Several studies have shown the superiority of renal scintigraphy over ultrasonography in detecting renal scars (Veenboer et al., 2015; Hitzel et al., 2002), however, ultrasonography remains a more feasible diagnostic test for regular surveillance imaging and may be suited to the noninvasive detection of larger cortical defects or renal size asymmetry (Merguerian et al., 1999).

Modern enhancements in ultrasound technology permit imaging of perfusion abnormalities in tissue. In reflux nephropathy using color Doppler ultrasonography, renal resistive index measurements derived from blood flow in interlobar and arcuate arteries are significantly increased in higher grades of reflux and correlate positively with scintigraphic findings from the same renal unit (Radmayr et al., 1999). Resistive indices are also higher in patients with pyelonephritis confirmed by nuclear scintigraphy compared with patients with lower UTI alone (Ozcelik et al., 2004). Animal studies have also demonstrated that contrast-enhanced harmonic ultrasonography can detect histologically confirmed regions of reflux-induced pyelonephritis with great sensitivity and more than 80% positive and negative predictive values (Farhat et al., 2002a, 2002b).

Renal Scintigraphy

The gold standard for functional imaging of renal parenchyma is scintigraphy using ^{99m}Tc-labeled DMSA. The radiotracer is taken up only by functioning proximal tubular tissue mass, where it binds for several hours. The uptake of DMSA provides a good proportional representation of glomerular filtration (Taylor, 1982). Renal scintigraphy should be standardized to capture function accurately and is useful clinically to dichotomize approaches when surgical intervention is considered, which rarely involve removal, from correction of VUR. Most institutions perform scans using a gamma camera positioned posteriorly, however, in cases with severe hydronephrosis, conjugate views may measure differential function more accurately (Pippi Salle et al., 2008; Wehbi et al., 2016). Because of the edema and inflammatory changes associated with pyelonephritis, tubular uptake of radiotracer is impaired, and these areas appear photopenic (Fig. 29.14). Although many such affected areas in the kidney resolve, especially with prompt medical treatment (Fernández-Menéndez et al., 2003), when they persist, irreversible renal damage or scarring is said to have occurred (Rushton and Majd, 1992). In a study of 79 children followed for 1 to 4 years, DMSA scanning provided 98% sensitivity and 92% specificity for scar detection (Merrick et al., 1980). Although Rushton's study suggested that subsequent scarring was independent of the presence or absence of VUR (Rushton and Majd, 1992), a meta-analysis found that reflux conferred an approximately threefold increased risk for detecting renal cortical abnormalities after infection (Faust et al., 2009; Pietrzak-Stelasiak et al., 2017; Nordenström, Holmdahl, et al., 2017a). Indeed, considering the overall incidence of pyelonephritis in children, VUR is present in 30% of such patients (Hoberman et al., 2003; Sargent, 2000). Nonetheless, the importance of VUR lies in the realization that it remains a spontaneously resolving or surgically treatable cause for this ascending group of renal infections (Rushton et al., 1991).

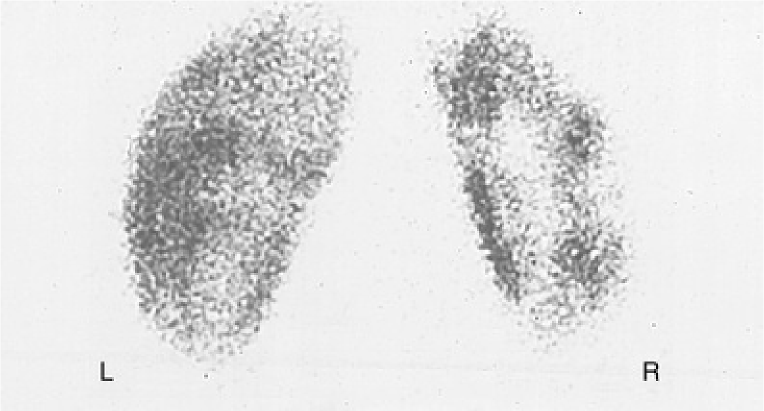

FIG. 29.14 Dimercaptosuccinic acid renal scintigraphy. Pinhole images show a normal left kidney and a right kidney with multiple cortical defects.

One advance in traditional nuclear scintigraphy of the kidneys is single-photon emission computed tomography (SPECT imaging). This approach reconstructs three-dimensional images of the renal cortical architecture, which can be viewed in any aspect in 360 degrees of rotation. Although SPECT images provide slightly higher sensitivity for detection of cortical defects, they do not add appreciably to standard pinhole DMSA images in the clinical management of reflux (Majd et al., 1996).

Despite the well-established guidelines for renal cortical scintigraphy from the Society of Nuclear Medicine (Mandell et al., 1997), investigators in the RIVUR study reported a significant degree of interinstitutional variability in how DMSA scans are performed, with 17% of RIVUR DMSA scans rejected because of poor quality (Ziessman et al., 2009).

Much has been written in the literature on the role of DMSA scanning in the management of VUR as an indirect investigation to the diagnosis of reflux itself, for the detection of reflux-associated renal damage and acute pyelonephritic changes, and for follow-up of reflux. DMSA and ultrasonography are often used complementarily, particularly when knowledge of relative renal function is desired (Riccabona et al., 1993). As a general rule, the utility of scintigraphy can best be appreciated in the context of the data it provides relevant to reflux: imaging cortical defects and relative renal function. The usefulness of this information will depend on what associated clinical and radiologic data are at hand. If reflux and infection history are unclear or unknown in a new patient referred for evaluation after UTI, scintigraphy can provide the gold standard for demonstration of cortical defects and help with counseling on additional studies. This serves the basis for the top-down approach (TDA), which is discussed later.

Confirmation of acute pyelonephritis can help ensure that adequate antimicrobial therapy is provided. If surgical intervention is planned and significant renal asymmetry exists on ultrasonography, quantification of relative function by scintigraphy can help in the decision between reflux correction and nephrectomy.

DMSA scanning also demonstrates congenital cortical maldevelopment, particularly in high-grade reflux, in the absence of any history of UTI or outlet obstruction (Wallin and Bajc, 1994; Nguyen et al., 2000). The distinction between congenital cortical defects and postinfection scarring is critical and may influence management decision making.

Controversies in Usage of Invasive Investigations

There are few conditions in pediatric urology more widely disputed with regard to diagnosis and management than VUR. A myriad of factors throughout essentially all aspects of the patient-parent-clinician interaction from diagnosis to surveillance to treatment exist.

The well-recognized distress of the family and patient associated with urethral catheterization, particularly in children, coupled with the advent of low-morbidity outpatient correction using endoscopic approaches has challenged conventional reflux management and therapy. Literature evaluating the utility of VCUG in the workup and diagnosis, as well as the role of medical management to prevent infection, is oftentimes conflicting.

All aspects of VUR have come under scrutiny, including incidence of renal scarring, association of VUR and renal failure, peak ages of susceptibility for renal scars, and indications for intervention, including the assumption that resolution or permanent correction of reflux is an absolute necessity. This has given rise to added pressures of avoiding bladder catheterization in view of the distress it creates in young patients (Stashinko and Goldberger, 1998; Elder, 2005).

Sedation (Stokland et al., 2003; Thacker et al., 2016; Blumberg, 2012), topical urethral anesthetic (Gerard et al., 2003), and hypnosis (Butler et al., 2005) have all been effective in mitigating the deleterious psychological effects of cystography.

Clinicians should resolve how each investigation, especially invasive ones, affects the overall clinical decision tree and how the results enable the safe management of each patient, either by intervention or conservative methods. All of this should be weighed against the degree of distress each test causes the child.

Renal Scintigraphy and the Top-Down Approach

The TDA is a concept based on the notion that only clinically relevant reflux with potential to cause renal injury is worthy of uncovering, with the critical assumption that VUR in the absence of scintigraphic renal abnormality is unlikely to cause future renal damage. As part of the initial workup, only a DMSA renal scan is obtained shortly after a febrile UTI, reserving a VCUG for patients with abnormal findings on renal scan. Essentially a DMSA scan is used to distinguish which children may benefit for workup to rule out VUR. In these cases, children with a negative DMSA scan undergo no further evaluation unless they develop recurrent UTI, in which case a VCUG should be obtained. If the significance or febrile nature of a potential pyelonephritis is unclear, particularly in a younger patient, a follow-up DMSA scan 4 to 6 months after UTI can rule out subsequent scarring, particularly if a normal scan exists from a prior evaluation. DMSA scanning can be particularly useful if the diagnosis of pyelonephritis is unclear during an acute infection.

Hansson et al. retrospectively reviewed 303 children younger than 2 years of age who had undergone evaluation by DMSA and VCUG within 3 months of their first UTI (Hansson et al., 2004). In this study, 82% of these infections were febrile, DMSA was abnormal in 51%, and VUR was found in 26% of the children (80/303), of whom 53 patients (66%) had abnormal DMSA scans; no abnormalities were detected in the remaining 27 patients. An approach based on identifying renal cortical abnormalities before obtaining a VCUG would have identified the 53 children with VUR presumably at risk for further scarring, and it would have excluded 120 children (40%) without VUR or renal abnormalities from an unnecessary VCUG.

Implementation of a TDA would obviously not have detected 34% (27/80) of the cases of VUR. However, in 74% of these patients VUR was low grade, and in the remaining 7 cases (grade 3 to 5 VUR, all of whom were on continuous prophylactic antibiotics) it either resolved or improved significantly during a 2-year follow-up period, with one patient developing a renal scar on repeat DMSA scintigraphy.

In a follow-up study from the same institution, Preda et al. prospectively confirmed these observations in 290 children younger than 1 year of age presenting with UTIs, of whom 79% were febrile (Preda et al., 2007). Positive scans were observed in 51%, including 85% (44 in 52) of the children found to have VUR. Of the 8 cases of VUR with normal DMSA scans, 7 were low grade, with one male patient having grade 3 VUR. There were no acquired renal scars on follow-up, despite one episode of BUTI.

Although several protocols advocate for an acute-phase and delayed-phase DMSA scan as part of the TDA, one study showed little clinical utility in the acute-phase scan as most irregularities of significance were seen on the delayed scan. They advised against an acute-phase DMSA scan during infection, as in this study, similar rates of febrile UTIs were found in patients with or without defects on the acute-phase DMSA scan (5%) (Kawai et al., 2017).

Although the TDA approach can decrease the number of VCUGs and detect more significant VUR, recent estimates based on robust data suggest test performance of DMSA to be less than historically presumed. One meta-analysis has shown that the TDA performs poorly at detecting high-grade VUR with a sensitivity and specificity of only 79% and 53%, respectively (Mantadakis et al., 2011). The most recent Cochrane review on the subject evaluating the summary sensitivity and specificity estimates of DMSA at detecting any VUR were 0.75 (95% CI, 0.67 to 0.81) and 0.48 (95% CI, 0.38 to 0.57), respectively, and 0.93 (95% CI, 0.77 to 0.98) and 0.44 (95% CI, 0.33 to 0.56) for high-grade VUR, respectively (Shaikh, et al., 2016b). In this meta-analysis, the authors concluded that DMSA scans lack the specificity to detect any VUR, even high-grade VUR. They also found that children with a normal DMSA scan have a less than 1% probability of having high-grade VUR (Shaikh et al., 2016b). However, the reverse is not true, because 70% of children with febrile UTIs would have positive findings on DMSA, therefore, inappropriately being labeled as high-risk.

A more recent report noted that because there have been access issues with acquiring DMSA scans in the acute setting, coupled with the higher radiation exposure, cost, and delay in treatment initiation, the TDA should be used on a risk-stratified basis, suggesting that efforts need to be directed to early and reliable identification of UTI, institution of effective treatment, and addressing BBD, as well as any other risk factors, as early as possible (Abdelhalim and Khoury, 2017).

In the TDA, DMSA scans are not intended to detect VUR per se, but merely aid in determining which patients with a history of UTI show enough evidence to support further evaluation with a VCUG.

Controversies in Usage of Invasive Investigations

National Institutes for Clinical Excellence Guidelines

In an attempt to streamline the investigations and treatment in infants and children presenting with UTI, the National Institutes for Clinical Excellence (NICE) in the United Kingdom proposed a set of guidelines aimed at reducing morbidity, antibiotic usage, and cost (The National Institute for Health and Care Excellence, 2018; Baumer and Jones, 2007). In infants younger than 6 months of age, investigations are limited to ultrasonography of the urinary tract, with cystography and DMSA reserved for those with “atypical” or recurrent UTIs. In patients older than 6 months but less than 3 years of age, a VCUG is recommended if the child has “atypical” or recurrent UTIs, which includes dilation on ultrasonography, poor urine flow, infection with non–*E. coli* bacteria, or family history of VUR. If a child in this age group responds well to treatment in 48 hours, no VCUG is indicated. Children older than 3 years of age should not have a routine VCUG ordered after a first UTI. The guidelines do not recommend early DMSA renal scan to confirm or exclude renal involvement and rely on RBUS in patients to determine the need for further investigation. The major criticism to this approach lies in the poor correlation between the appearance of the kidneys on ultrasonography and the presence of renal parenchymal changes or the presence and grade of VUR (Shaikh et al., 2016b; Hung et al., 2016). One study that used a historical cohort of 43 patients 2 to 24 months of age with ultrasonography, VCUG, and renal scans applied the NICE guidelines and found that they would have missed 63% of the children with VUR grade II and above, including a high proportion of grades IV and V, 44% of the children with renal scarring, and 20% of the children with decreased renal uptake, including some children with bilateral renal scarring and with decreased renal function (Narchi et al., 2015). In a similar study with 98 infants, had the NICE guidelines been applied, that is, only those with an abnormal RBUS would have been further investigated, 25 refluxing ureters and 22 scarred kidneys would have been left undiagnosed (Tse et al., 2009).

Taken together, an oversimplified approach that does not take into account the broader spectrum of patients with varying risks for future infections and the impact of VUR limits the applicability of these recommendations. They fail to address key differences, which exist between children in clinical practice at presentation. Moreover, the NICE committee did not provide any robust clinical outcomes to validate these guidelines or confirm the safety of this approach, and thus its use in general clinical practice should be with caution.

American Academy of Pediatrics Guidelines for Febrile Urinary Tract Infection Diagnosis and Management in Young Children

In 2011, the AAP released revised guidelines for the diagnosis and management of febrile UTI in children 2 to 24 months of age (Subcommittee on Urinary Tract Infection, Steering Committee on Quality Improvement and Management, and Roberts, 2011). The guidelines were developed after a rigorous review of the literature including six randomized controlled trials of CAP to prevent recurrent UTI. The guidelines are summarized in Table 29.5.

TABLE 29.5

American Academy of Pediatrics Clinical Practice Guideline on Febrile Urinary Tract Infection in Febrile Infants and Young Children: Key Updates

AREA OF MANAGEMENT	UPDATES FROM THE 1999 GUIDELINE
Diagnosis	Both an abnormal urinalysis result and a positive urine culture result are needed to confirm inflammation
	A positive culture result is defined as at least 50,000 colony-forming units per milliliter, rather than the previous criterion of at least 100,000 colony-forming units per milliliter
	Guidance is added for using clinical criteria to establish a threshold to decide whether to obtain a urine specimen
Treatment	Oral treatment is as effective as parenteral treatment
Imaging	Voiding cystourethrography is not recommended routinely after the first febrile urinary tract infection; ultrasonography should include the bladder and kidneys
Follow-up	Emphasis is on urine testing with subsequent febrile illnesses, rather than on regularly repeated urine cultures after treatment

Note: The guideline applies to infants and children 2 to 24 months of age with unexplained fever.

Data from Subcommittee on Urinary Tract Infection, Steering Committee on Quality Improvement and Management, Roberts KB. Urinary tract infection: clinical practice guideline for the diagnosis and management of the initial UTI in febrile infants and children 2 to 24 months. *Pediatrics*. 2011;128(3):595–610.

To establish the diagnosis, stricter criteria for the diagnosis of infection were suggested, including a lowered threshold for urine culture colony-forming units per milliliter (50,000 from 100,000) and the additional requirement of an abnormal urinalysis. Oral and parenteral antibiotic treatments are now considered equally effective. The use of RBUS retains its traditional and important role in structural assessment. **The inconclusive lack of efficacy of CAP in preventing UTI and renal injury led to the most significant deviation from past practice, the recommendation to forgo VCUG after the *first* febrile UTI unless indicated by any abnormal RBUS findings or after a subsequent febrile UTI.**

If hydronephrosis, findings suggestive of renal scarring/dysplasia, or obstructive uropathy are present, a VCUG should be obtained. Similarly, any complex or clinically atypical scenario supports obtaining a VCUG after the first febrile UTI. These recommendations attempt to balance the risk for missing clinically significant VUR after a first febrile UTI in infants, against the invasiveness, radiation exposure, and patient and family anxiety surrounding VCUG.

The Section on Urology of the AAP guidelines disagreed with some of these recommendations in view of the quality of the studies cited. Some of the critical issues were related to inclusion of data from underpowered studies, nonuniform urine-collection techniques, not accounting for either the role of bladder and bowel dysfunction or the link between VUR and renal scarring, and lastly, assuming the presenting infection was truly the first clinically significant infection (Wan et al., 2012).

Undoubtedly the AAP recommendations have resulted in a significant reduction in the number of children undergoing VCUG, however, the guidelines fail to address the need for an individualized, risk-based approach to treating children with suspected VUR.

Associated Anomalies and Conditions

Ureteropelvic Junction Obstruction

VUR and UPJO are two of the most common pathologic conditions in pediatric urology. Thus it is not unusual that these two conditions coexist. Whether the concomitant presence of these two conditions is a random event or is causally related remains unclear. It has been speculated that a developmental ureteric bud anomaly may be responsible for the imperfect formation of both the UVJ and the UPJ (Bomalaski et al., 1997).

The incidence of VUR associated with UPJO ranges from 0.6% in historical studies (Bomalaski et al., 1997) **to as high as 5.2% to 8.2% in more contemporary studies** (Weitz and Schmidt 2016; ElSheemy et al., 2017). When the two conditions were primarily present, most of the patients in these studies had reflux that was coincidentally discovered, was of low grade, and resolved spontaneously with time. A significant limitation to several published studies includes their retrospective nature. Such patients typically exhibited a significant discrepancy between the minimal degree of ureteral dilation and the significantly dilated renal pelvis. Thus the apparent grade of reflux may be overestimated, and management decisions based on the grade of reflux are inaccurate at best. Conversely, the incidence of UPJO in patients with reflux ranges from 0.75% to 3.6% (Lebowitz and Blickman, 1983; Bomalaski et al., 1997), with high-grade reflux being five times more likely to be associated with UPJO than lower grades of reflux (Lebowitz and Blickman 1983; Bomalaski et al., 1997). Indeed, in one study of children with reflux and hydronephrosis, 50% of high-grade sonographic hydronephrosis, commonly associated with the highest grades of reflux, showed an obstructive pattern on furosemide (Lasix) scintigraphy (Stauss et al., 2003).

Three radiologic signs might suggest the existence of UPJO in the setting of reflux. First, if the pelvis shows little or no filling while the ureter is dilated by contrast, this may indicate a point of kinking secondary to reflux or from a primary UPJO (Fig. 29.15). Second, contrast that enters the pelvis may be poorly visualized because of dilution in a large pelvic volume and exhibits markedly lower radiodensity compared with the ureter or bladder. Finally, a large pelvis that fails to drain promptly and retains contrast postvoid is also suggestive of UPJO.

FIG. 29.15 Reflux and ureteropelvic junction (UPJ) obstruction. (A) Significant reflux fills the left ureter to the level of the UPJ. Minimal filling of the pelvis can be a sign of obstruction at this level. (B) In a different patient, reflux is seen as the bladder fills. (C) Significant kinking of the UPJ occurs with voiding.

Radiographic studies of UPJO associated with VUR may indicate true anatomic obstruction or simply dilation caused by pelvi-ureteral dilation in higher grades of reflux. Hollowell et al. referred to three clinical categories of concomitant obstruction and reflux (Hollowell et al., 1989). Group 1 had primary UPJO and incidental low-grade reflux, and group 2 had secondary UPJO from high-grade reflux. These two groups represent true anatomic obstruction for which pyeloplasty is recommended. Group 3 represents only significant dilation of the upper tracts without obstruction, which is confirmed by documenting good drainage on postvoid images at cystography or by renal scintigraphy.

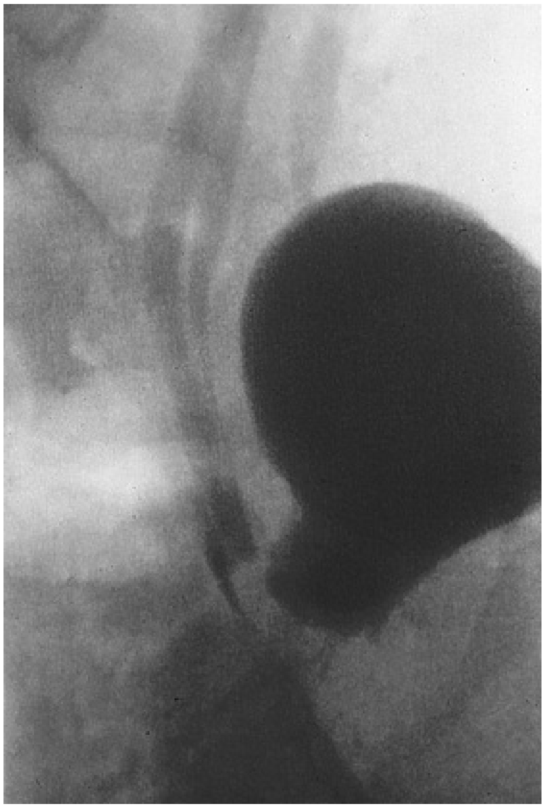
The cause of secondary UPJO is unclear. Several factors are thought to predispose or even aggravate a potential narrowing at the level of the UPJ. High-grade reflux may result in kinking of the upper ureter and adjacent pelvic junction. The chronic effects of high-grade reflux also may passively stretch the renal pelvis so that atonicity and an inability to propel urine through the UPJ may occur (Whitaker 1973). In the setting of UTI propagated to the upper tracts by reflux, inflammation and ureteritis can also contribute to transient or chronic obstruction at the UPJ.

The convergence of two ureteral anomalies in the same patient raises additional management questions in the situation in which treatment of one anomaly may affect the natural history of the other. **Nevertheless, the guiding therapeutic principle is the preservation of renal function. Sterile reflux can be safely observed, however, obstruction even in the absence of infection may jeopardize renal function. Therefore, in the presence of reflux, if scintigraphy with catheter drainage confirms UPJO, correction of obstruction takes precedence over surgical repair of VUR.** The secondary insult to the UPJ from reflux is an evolving process that cannot be efficiently or adequately corrected by surgical repair of the reflux itself. Furthermore, reflux correction alone risks amplifying upper tract dilation caused by postoperative edema in the lower ureter and risks introducing infection to the obstructed renal pelvis.

The simultaneous open correction of UPJO and reflux has always raised concern over surgical manipulation of both the upper and lower ureter at the same time and its potential negative impact on ureteral vascularity. However, endoscopic VUR correction at the time of pyeloplasty for secondary or primary UPJO is a reasonable option despite its lower success rate.

Ureteral Duplication

VUR is the most common abnormality associated with complete ureteral duplications. The embryologic origin of the duplicated ureter supports the observation that reflux occurs most commonly into the lower pole. This relationship is based on the studies of Weigert and Meyer, who documented the more lateral and proximal insertion of the lower moiety ureter associated with a shorter intramural ureter resulting in an incompetent UVJ (Weigert 1877; Meyer 1946) (eFig. 29.16).

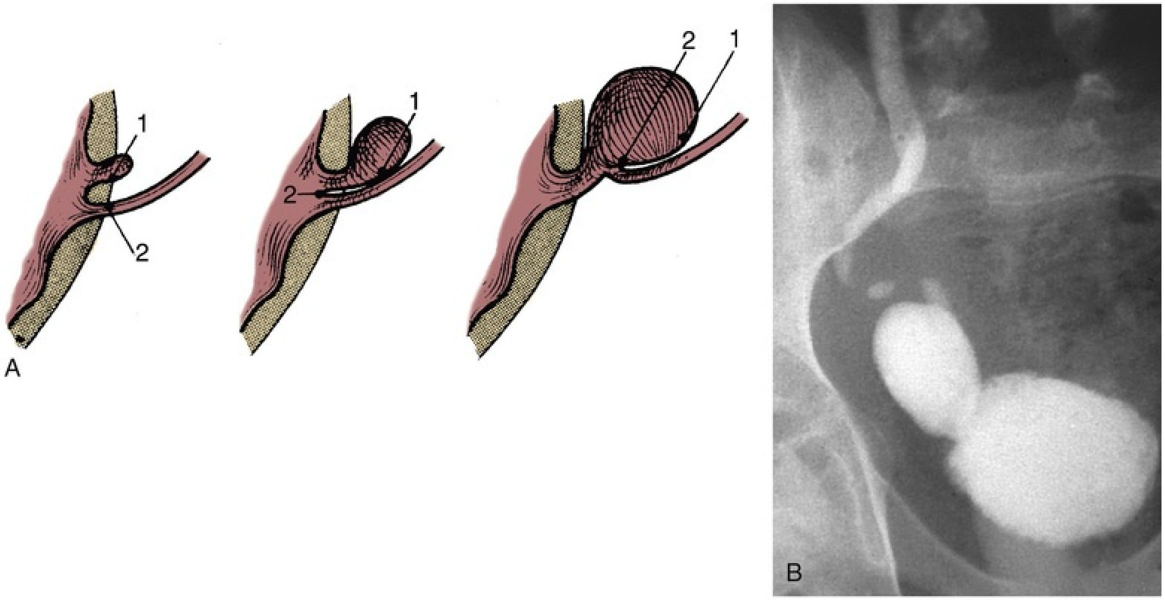


EFIG. 29.16 Reflux into both ureters of a complete duplication, as shown here, is less common than reflux into the lower pole ureter alone.

The incidence of reflux is increased in patients with complete ureteral duplication (Privett et al., 1976). Earlier studies provide a limited view of whether reflux in a duplex moiety carries increased patient risk because of the lack of control groups, arbitrary patient selection, and short follow-up. Traditionally, the tendency was to recommend VUR correction in patients with complete duplication and low-grade reflux as it may take longer to resolve compared with single-system VUR (Estrada et al., 2009a). However, the observation that duplication is not associated with risk for increasing grade, BUTI, or scarring (Husmann and Allen 1991) makes conservative management a more reasonable option (Lee et al., 1991; Peppas et al., 1991). In a series of 105 patients with complete duplication, 36% were managed nonoperatively with spontaneous rates of reflux resolution of 85% for grades I and II, and 36% for grade III (Lee et al., 1991). A more recent series supports this finding in low-grade reflux but notes that high-grade reflux into lower pole ureters in females is more prone to BUTI and scarring and therefore may warrant more aggressive management (Estrada et al., 2009a; Afshar et al., 2005b).

Bladder Diverticula

A full discussion of bladder diverticula is found elsewhere in this text. The outpouching of mucosa between detrusor muscle bundles, which lacks any true muscle backing itself, commonly defining a bladder diverticulum, has the theoretic potential to affect the natural history of VUR in two ways. Most commonly, if the UVJ is distorted by a paraureteral diverticulum, which shares an anatomic point of origin at or near the UVJ, it is possible that the diverticulum could compromise the antireflux configuration of the UVJ to cause reflux (eFig. 29.17). Neither cystoscopy nor imaging is predictive of whether paraureteral diverticula truly compromise the resolution of reflux, as has been commonly believed. Hutch was the first to recognize that bladder diverticula were congenital abnormalities that occurred primarily in smooth-walled normal bladders in children (Hutch, 1952). Several retrospective studies demonstrate the high rates of VUR in the presence of a paraureteral bladder diverticulum and in a series of 131 children with 202 refluxing ureters, 27% had a periureteral diverticulum (Im et al., 2015). In addition, the risk for recurrent UTIs increased in ureters with paraureteral diverticulum (odds ratio 3.1, $p = 0.020$) (Im et al., 2015).



EFIG. 29.17 (A) Schematic representation of a bladder diverticulum *(2)*. A small amount of mucosa initially herniates through a congenital defect in the bladder musculature. The defect enlarges with voiding. Finally, the ureteric orifice *(1)* is incorporated into the diverticulum. (B) Reflux into a right-sided paraureteral diverticulum and ureter seen on voiding cystography. (A, From Hernanz-Schulman M, Lebowitz RL. The elusiveness and importance of bladder diverticula in children. *Pediatr Radiol*. 1995;15[6]:399–402.)

However, another retrospective cohort analysis of 84 patients with paraureteral diverticula and reflux showed no significant difference in spontaneous resolution rates (60%, 39%, and 22% for grades I to II, III, and IV to V reflux with paraureteral diverticulum vs. 52%, 28%, and 33% in a matched control group of 95 patients with reflux without diverticulum). Rates of UTI and scarring were similar in both groups. Multivariate analysis revealed reflux grade to be the only predictor of resolution in both groups (Afshar et al., 2005a). Thus **reflux associated with paraureteral diverticula resolves at rates similar to that of primary reflux and should be managed according to the prevailing indications for the reflux itself, irrespective of the diverticulum.** However, when a refluxing ureter enters a diverticulum, the latter is no longer paraureteral. With no muscular support to the UVJ, reflux is not expected to resolve. In a given patient, indications for repair require the combined consideration of the potential impact of unresolved reflux, if any, along with whether the diverticulum itself is of sufficient size or conformation to incite complications.

Renal Anomalies

By definition, primary reflux represents dysfunction of the UVJ. Because the development of both the UVJ and the kidney itself are linked to the origin and fate of the ureteral bud, it is reasonable to consider the existence of reflux whenever an anomaly of renal form or number is present. **Significant renal anomalies associated with reflux are multicystic dysplastic kidney (MCDK) and renal agenesis.** In the largest series to date, 75 patients with MCDK showed a prevalence of contralateral reflux of 26% (19 patients), and one-half of these were low grade (1 to 2) (Miller et al., 2004). Spontaneous resolution occurred in a mean of 4.4 years, regardless of grade. Only one patient had reflux corrected surgically. In a small series of ureteral ectopia, one patient with MCDK had the contralateral ureter enter into the ductus deferens (Wunsch et al., 2000), further underscoring the importance of documenting the contralateral kidney's ureteral conformation in patients with MCDK. Although contralateral renal growth often displays compensatory hypertrophy, one study observed somewhat less compensatory hypertrophy by 1 year of age (Zerin and Leiser, 1998) than may be expected if contralateral reflux is absent (5.1 vs. 6.2 cm median renal lengths, $P < .001$).

Renal agenesis is associated with an even higher prevalence of contralateral anomalies. Several studies have shown that in children with solitary renal agenesis, the rate of contralateral renal pathology varies from 32% to 46%. VUR was by far the most common contralateral defect ranging from 24% to 28%, with UVJ and UPJO seen in 11% and 6% to 7%, respectively (Cascio et al., 1999; Westland et al., 2013). In another study, 19 cases of contralateral reflux were observed in 51 patients with ipsilateral renal agenesis (Song et al., 1995). Reflux repair or persistence was documented in 9 and 7 patients, respectively, with spontaneous resolution observed in only 3 patients. Whether renal agenesis represents one extreme on a continuum that includes MCDK is unclear. Nevertheless, these data suggest that contralateral reflux associated with renal agenesis may show less tendency to spontaneous resolution than that associated with MCDK.

Megacystis-Megaureter Association

Massive bilateral VUR can cause a gradual remodeling of the entire upper urinary tract. The gross inefficiency of the bladder that expels urine to both the exterior and the upper tracts results in gradual bladder dilation as the refluxed urine returns to the bladder. This perpetuates marked ureteral dilation, leading to the radiographic appearance of massive hydroureter and a thin-walled enlarged bladder (Burbige et al., 1984). The phenomenon is referred to as the *megacystis-megaureter association* or syndrome. This configuration is even discernable in utero (Mandell et al., 1992). It is more frequent in males, and the differentiation from posterior valves is crucial (Kaefer et al., 1997). Although the latter is caused by an obstructive lesion, megacystis-megaureter is a nonobstructive condition akin to cardiac dilation by regurgitation from incompetent valves. Voiding studies will readily demonstrate an open posterior urethra and differentiate megacystis-megaureter from posterior valves or prune-belly syndrome. The persistent large residual urine volume is a significant risk factor for recurrent UTI. Vesicostomy can temporize by eliminating the residual urine volume and establishing safe drainage of the upper tracts until ureteral reimplantation can be performed. Given the propensity for reflux to exacerbate the effects of bacteriuria and the fact that UVJ dysfunction is the primary factor perpetuating the syndrome, surgical correction for the reflux is generally indicated. Treatments aimed at improving an already patent bladder outlet are contraindicated, risk infection, and fail to correct the primary cause. A period of bladder rehabilitation by strict attention to emptying in the postoperative period (Koefoot et al., 1981) usually will result in a return to normal bladder volume and contractile behavior. This suggests that potentially normal underlying bladder physiology can be realized if the propensity for reflux is corrected.

Other Anomalies

VUR also has been described in association with a number of congenital conditions and syndromes. No precise common genetic insult has been determined to explain such associations. A complete survey of the Online Mendelian Inheritance in Man Database developed by Johns Hopkins University, maintained by the National Center of Biotechnology Information, reveals more than 40 different syndromes in which VUR has been described (http://www.ncbi.nlm.nih.gov/Omim/getmap.cgi?l193000). These include the VACTERL association (*V*ertebral, *A*nal, *C*ardiac, *T*racheo*E*sophageal, *R*enal, and *L*imb anomalies), CHARGE syndrome (*C*oloboma, *H*eart disease, *A*tresia choanae, *R*etarded development, *G*enital hypoplasia, and *E*ar anomalies), and imperforate anus. In cases in which VUR is anticipated, a VCUG is the initial study of choice to disclose both dysfunction at the UVJ and overall bladder and bladder outlet anatomy.

Pregnancy and Reflux

The morphology of the urinary tract is altered with the onset of pregnancy and increases throughout gestation (Beydoun 1985). **Bladder tone decreases because of edema and hyperemia, changes that predispose the patient to bacteriuria. In addition, urine volume increases in the upper collecting system as the physiologic dilation of pregnancy evolves.** The slower drainage that results can enhance the growth of organisms and increase the propensity to develop pyelonephritis. It seems logical to assume that during pregnancy the presence of VUR in a system already prone to bacteriuria would lead to increased morbidity. A number of studies have been conducted to examine this relationship.

The presence of active reflux appears to present a risk factor for the affected mother. In 1958, Hutch described a higher incidence of pyelonephritis during pregnancy in 23 women with a history of reflux and recurrent bacteriuria (Hutch et al., 1963). Heidrick et al. evaluated 321 women with cystography either during the last trimester or within 30 hours after delivery (Heidrick et al., 1967). The incidence of pyelonephritis was 33% in women with reflux compared with less than 5% in women without reflux. Finally, cystograms performed 4 to 6 months postpartum in 100 women with a history of asymptomatic bacteriuria during pregnancy showed reflux in 21%. Bacteriuria was easier to clear in patients without reflux (67%) than in those with reflux (33%) (Williams et al., 1970).

Maternal history also becomes a factor if past reflux, renal scarring, or a tendency to UTIs is included. Martinell et al. compared the outcome of pregnancy in matched controls with that in 41 women with and without renal scarring after childhood UTIs (Martinell et al., 1990). They found that women with a history of prior infections had a high incidence of bacteriuria during pregnancy, whereas those with renal scarring and persistent reflux were more prone to develop acute pyelonephritis. In a similar study, the outcome of pregnancy was assessed in 88 women with previous bacteriuria. Women with known scars had a 3.3-fold increased incidence of hypertension, a 7.6-fold increased risk for preeclampsia, and a higher rate of obstetric interventions. Women with normal kidneys and reflux also had an increased risk for hypertension during the last trimester (McGladdery et al., 1992). Pregnant women with bilateral renal scars were also shown to have a higher incidence of preeclampsia than those with unilateral scarring (24% vs. 7%, respectively) (El-Khatib et al., 1994), and those with creatinine elevation are also at risk (Jungers et al., 1987). In a large study of 158 women with reflux nephropathy, pregnancy was uneventful in patients with normal blood pressure and renal function, whereas the risks for fetal demise and accelerated maternal renal disease were increased in women with impaired renal function (Jungers, 1996).

Another study evaluated pregnancies in women with a history of VUR and found that those with renal scars had an almost 2.5 times higher rate of hypertension during pregnancy and almost twice the rates of proteinuria (Roihuvuo-Leskinen et al., 2015).

Austenfeld and Snow studied the implications of reimplantation surgery and found an increased risk for UTI and fetal loss in 31 women who had undergone ureteral reimplantation as children, despite correction of the anomaly (Austenfeld and Snow, 1988). In a follow-up study comparing these patients with a new cohort of historical controls, women with UTIs and reflux who underwent reimplantation (suggesting an initially higher degree of reflux and increased renal scarring) were still at significant risk for UTI during pregnancy (Mansfield et al., 1995). However, they were not at a higher risk for miscarriage than the general population. In a larger study of 77 pregnancies in 41 women whose ureters had been reimplanted, Bukowski et al. reported that the incidence of pyelonephritis during pregnancy was slightly higher than in the general population but that the fetus and mother were at significant risk when renal scarring or hypertension was present (Bukowski et al., 1998). Although these studies may at first suggest a limited benefit to reimplantation during a subsequent pregnancy, several factors must be borne in mind. None of these studies document any associated BBD in these women, which may have existed in childhood and continued unrecognized into the fertility years. Also, bladder dynamics change during pregnancy as a result of increasing uterine size. Although it is assumed that reflux remains absent during pregnancy after correction in childhood, radiologic verification that the surgically corrected UVJ remains competent (reflux free) is not feasible, and such data are not available. Finally, it is not known whether formerly refluxing renal units in such adult patients carry a latent predisposition or heightened susceptibility to pyelonephritis during the pregnancy as a consequence of previous postinfection damage during childhood and/or any inherent reflux-associated dysplasia, both of which would persist despite surgery at the bladder level. Nevertheless, in keeping with the more recent emphasis on preexisting renal status when considering reflux management, at least one meta-analysis of the significance of a pregnancy and reflux association also suggests that the presence of renal scarring, and not the presence or absence of reflux, is the principal factor driving morbidity during pregnancy in such women (Hollowell, 2008). When combined with the known physiologic renal and bladder changes during pregnancy, it is reasonable to speculate that such kidneys may carry a heightened predisposition to pyelonephritis.

In summary, the majority of studies examining the effects of VUR on pregnancy suggest that women with a history of reflux have increased morbidity during pregnancy because of infection-related complications, whether the reflux has been corrected or not. Women with hypertension and moderate renal impairment are also at risk for preterm birth. In addition, 43% of their offspring who underwent a VCUG had VUR (North et al., 2000).

The morbidity during pregnancy of women with persistent reflux without renal scarring remains poorly defined, but the tendency to UTI seems to be increased. Because of the difficulty in predicting an outcome for this subset of patients, some clinicians recommend surgical correction for girls with reflux that persists beyond puberty, although there has been a trend toward discontinuation of prophylactic antibiotics in older girls with active reflux and close monitoring. Long-term follow-up studies of these patients through puberty are unavailable.

Key Points: Pregnancy and Reflux

- Physiologic changes in the ureter and bladder during pregnancy may influence the propensity for reflux-associated pyelonephritis in pregnant patients with reflux.
- In the absence of definitive studies to the contrary, correction of reflux may be considered before pregnancy.

Natural History and Management

Spontaneous Resolution

The one feature of VUR that provides the greatest relief to parents and at the same time creates confusion in reflux study design and literature interpretation is spontaneous resolution. Traditionally, the basis of medical therapy was predicated on an expected rate of spontaneous resolution. At birth, the probability of spontaneous resolution of primary reflux is roughly inversely proportional to the initial grade. If a patient is encountered at a later age, resolution from any point in time forward will depend on initial grade of reflux, if it is known, and age at presentation.

Reflux likely resolves spontaneously as a result of remodeling of the UVJ over time, with progressive elongation and consolidation of the intravesical ureter and antireflux mechanism and stabilization of bladder dynamics. Conversely, failure to achieve normal bladder and bowel function likely accounts for reflux persistence beyond the statistical norms in many patients.

Resolution by Grade

Most cases of low-grade reflux (grade I and II) will resolve. Several studies have documented this high rate of spontaneous resolution. However, the variance in several reported studies for resolution rates for grade 2 reflux was 63% (Duckett, 1983), 80% (Arant, 1992), and 85% (Edwards et al., 1977). This belies the fact that lower urinary tract dynamics may also play a role in mitigating spontaneous resolution.

Grade 3 reflux will resolve in approximately 50% of cases (Duckett 1983; McLorie et al., 1990). Very few cases of higher-grade reflux (grades 4 and 5, and bilateral grade 3) will resolve spontaneously. Analyses from several sources, including the International Reflux Study in Children, support a uniformly low likelihood of resolved high-grade reflux, with no more than 25% (Weisset al., 1992a) and as little as 9% (Skoog et al., 1987) of patients demonstrating spontaneous resolution. In another study of children younger than 1 year of age who were diagnosed with high-grade reflux 4 and 5, there was a slightly higher resolution rate of 35.7% (5 of 14 renal units) (Wildbrett et al., 2013).

In one of the largest retrospective series to date, Estrada et al. generated nomograms to predict spontaneous resolution rates based on several factors including grade. With almost 2 years of follow-up, resolution rates for grades 1, 2, 3, and 4/5 were 72%, 61%, 49%, and 32%, respectively (Estrada et al., 2009a). Clearly there are shortcomings to even large retrospective studies, especially with a significantly higher proportion of patients in the higher-risk groups having undergone surgery, which may bias the data. Considering the fact that any given reflux grade is assigned on the basis of a dynamic voiding study, the possibility for variations by at least one grade, especially in assigning higher grades of reflux, is quite real. Thus, attempting to discriminate true differences in resolution rates for grades 3 and higher reflux may not be particularly clinically relevant.
